ELINA BERNTSSON

TALLINN UNIVERSITY OF TECHNOLOGY

School of Science

Department of Chemistry and Biotechnology

This dissertation was accepted for the defense of the degree of Doctor of Philosophy in Gene Technology on 20/12/2024

**Supervisor:** Prof. Peep Palumaa  
Department of Chemistry and Biotechnology  
Tallinn University of Technology  
Tallinn, Estonia

**Co-supervisors:** PhD. Sebastian Wärmländer  
Cellpept Sweden AB  
Stockholm, Sweden  
  
PhD. MD. Per M Roos  
Department of Clinical Neuroscience  
Karolinska Institute  
Stockholm, Sweden

**Opponents:** Prof. Jan Johansson  
Department of Medicine  
Karolinska Institute  
Stockholm, Sweden  
  
Prof. Ago Rinken  
Institute of Chemistry  
University of Tartu  
Tartu, Estonia

**Defence of the thesis:** 31/01/2025, Tallinn

**Declaration:**

Hereby I declare that this doctoral thesis, my original investigation and achievement, submitted for the doctoral degree at Tallinn University of Technology has not been submitted for doctoral or equivalent academic degree.

## Introduction

Alzheimer's disease (AD) is one of the most prevalent neurodegenerative disorders and the most common form of dementia worldwide. Despite decades of research, many details about AD pathogenesis remain unclear.

Aggregation of the amyloid- $\beta$  (A $\beta$ ) peptide is one of the hallmarks of AD, and is believed to cause neurotoxicity and synaptic dysfunction, leading to neuronal death and cognitive decline. A $\beta$  aggregates are formed when monomeric A $\beta$  peptides misfold and convert from a random coil structure into a  $\beta$ -pleated-sheet-rich structure, which is more prone to aggregation. The peptides assemble from monomers into oligomers, protofibrils and finally into a mature fibril exhibiting cross- $\beta$  structure, where the  $\beta$ -strands run perpendicular to the fibril axis.

Several factors have been implicated in the aggregation mechanism and toxicity of A $\beta$ . One such possible factor is interactions with metal ions. Metals such as copper, iron and zinc are abundant in the brain and are required in many physiological processes. Importantly, dysregulation of metal homeostasis has been linked to AD pathogenesis. Maintaining metal homeostasis in the body is crucial, as increased metal ion levels can generate reactive oxygen species (ROS), leading to increased oxidative stress damaging cellular components and contribute to neurodegeneration. In addition, metal ions may directly interact with the A $\beta$  and affect its aggregation.

It is well known that the A $\beta$  aggregation process is sensitive to environmental changes. Minor variations in temperature, pH, peptide concentration, agitation, etc. may have large effects on the aggregation rate and the morphology of the formed aggregates. Therefore, it is not surprising that binding of charged metal ions typically affects the aggregation pathway of the peptide. Metal ions have been shown to modulate peptide aggregation by promoting aggregation of monomeric peptides into fibrils, but also by stabilizing aggregates in the most toxic oligomeric states. Metals such as copper and nickel ions have in this thesis been shown to bind to the A $\beta$  N-terminal, where histidines are implicated as binding residues. In contrast, metal compounds such as the uranyl ion have been shown to interact with the peptide without residue-specific binding, instead affecting the peptide via electrostatic interactions.

Although the A $\beta$  peptide is the most prevalent component of amyloid plaques in AD brains, other proteins such as Apolipoprotein E (ApoE) may also be relevant for the AD pathogenesis. One isoform of the ApoE protein, ApoE4, is known to increase the risk for developing AD, up to four-fold in heterozygotic carriers and up to twelve-fold in homozygotic carriers. Another isoform, ApoE2, seems to protect against the disease. A further interesting aspect of the ApoE protein, in relation to AD and metals, is that carriers of the ApoE4 allele have been shown to be more susceptible to mercury toxicity. It has therefore been suggested that the ApoE protein may play a role in the clearance of mercury, and perhaps also the A $\beta$  peptide.

The aim of this study was to improve the understanding about the role of metal binding in AD pathology. A wide range of spectroscopic methods have been used to investigate the interactions between metal ions and AD related proteins. Although some metals in this study might not be required for biological function, they all occur in the environment and exposure is known to cause toxicity and interfere with normal neurological function. Obtained results widen our insight into the role of metal ions in AD pathology.

## Abbreviations

A $\beta$	Amyloid- $\beta$
ACh	Acetylcholine
AD	Alzheimer's disease
AFM	Atomic force microscopy
ALS	Amyotrophic lateral sclerosis
ApoE	Apolipoprotein E
APP	Amyloid precursor protein
ATCUN	Amino-terminal Cu(II) and Ni(II) binding motif
BBB	Blood brain barrier
CAC	Critical aggregation concentration
CD	Circular dichroism
CNS	Central nervous system
CSF	Cerebrospinal fluid
fAD	Familial Alzheimer's disease
HD	Huntington's disease
HSA	Human serum albumin
NFT	Neurofibrillary tangle
NMR	Nuclear magnetic resonance
PD	Parkinsons disease
PSEN	Presenilin
ROS	Reactive oxygen species
sAD	Sporadic Alzheimer's disease
TBI	Traumatic Brain Injury
TEM	Transmission electron microscopy
ThT	Thioflavin T

# 1 Background

## 1.1 Folding of proteins

Understanding the basic properties of polypeptide chains is fundamental to comprehending how proteins achieve their diverse functions within biological systems. The primary structure of native proteins usually folds rapidly into a secondary structure, and then into a tertiary three-dimensional structure, largely affected by the properties of the amino acid residues and the surrounding environment to ensure functionality and achieve a state of lowest free energy. The secondary structure of a protein refers to the local folding patterns, where alpha helices and beta sheets are the two most common structures. Both are stabilized by hydrogen bonds between the backbone of the polypeptide chain(s). When a protein or a region of a protein does not form a stable, regular secondary structure, and instead exists in a flexible, disordered and irregular conformation, it is said to be in a random coil structure (Zorko, 2010).

Folding of proteins is driven by various molecular interactions. Van der Waals forces are weak interactions that occur between closely packed atoms, and they help to stabilize folded structures. Disulfide bridges, typically formed by oxidation of cysteine residues, can covalently link distant parts of polypeptide sidechains and thereby further enhance structural stability. Salt bridges can stabilize the structure of a protein by interactions between two oppositely charged amino acids, often arginine or lysine binding to aspartic or glutamic acid. Hydrophobic effects are crucial for reducing the free energy of a system, and it is common that proteins form a hydrophobic core, where nonpolar hydrophobic residues are shielded from the aqueous, polar environment.

Factors such as mutations, translational errors, environmental stress, aging etc. may interfere with the protein folding process. This interference may yield misfolded proteins, which are characterized by deviations from their native, functional three-dimensional conformation. Although human cells have multiple control systems that screen for misfolded proteins, and attempt to correct or degrade them, these systems can sometimes fail. When this happens, misfolded proteins can aggregate, disrupt cellular processes and contribute to the pathology of disease.

## 1.2 Neurodegeneration

Neurodegenerative diseases are a group of conditions which mainly impact neurons in the brain. The most frequently occurring examples of such diseases are Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD) and Amyotrophic lateral sclerosis (ALS). Although all neurodegenerative diseases are different in their specific features, they share several common pathological features, where progressive loss of neurons, synaptic dysfunction, and loss of synaptic connections are the most prominent (Ciurea et al., 2023; Hussain et al., 2018). As different diseases affect different areas of the brain, the symptoms will vary, although it is common to observe cognitive decline, motor dysfunction and behavioral changes in patients (Montero-Odasso et al., 2017; Trojsi et al., 2018). Many neurodegenerative diseases also have a long presymptomatic phase, when changes in the central nervous system (CNS) have started, but no symptoms are yet present in the patient. This makes it difficult to detect and treat the disease before substantial damage already has been made (Katsuno et al., 2018).

Extensive research has been conducted for decades in the field of neurodegeneration, but the underlying mechanisms and many details of the pathogenic mechanisms are for most diseases still not understood.

### **1.2.1 Proteinopathies**

Many neurodegenerative diseases are categorized as proteinopathies, also known as protein conformational diseases. It is a class of diseases characterized by misfolding and aggregation of proteins, resulting in loss of function and/or toxic properties (Bayer, 2015; Noor et al., 2021). Proteinopathies primarily affect the CNS and manifest with a range of symptoms related to CNS dysfunction. Some proteinopathies involve multiple organs and peripheral tissues (Brito et al., 2023; Gertz, 2022; Sack, 2020), these will not be considered in this thesis.

In neurodegenerative proteinopathies (henceforth only called proteinopathies), proteins undergo structural modifications that lead to self-association, elongation, and aggregation into fibrillar structures that can accumulate in the CNS. Molecular processes such as disruptions in protein clearance, post-translational modifications or increased protein production can be observed in several proteinopathies (Bayer, 2015; Ciccocioppo et al., 2020). Many of the proteinopathies are complex and involve more than one type of aggregating protein, which often complicates diagnosis and the development of effective therapies. List of neurodegenerative proteinopathies and related proteins is presented in Table 1.

#### **1.2.1.1 Amyloid formation**

In the mid-19<sup>th</sup> century, researchers first described iodine stainable brain deposits found during autopsies. It was therefore assumed that the deposits consisted of starch, and they were consequently named “amyloid” (derived from the Latin word ‘amylum’, meaning starch). When the deposits were further studied, a high nitrogen content was detected, which prompted a re-interpretation that resulted in a suggestion that the deposits to a large extent consisted of proteins (Cohen, 1986; Sipe & Cohen, 2000).

Today the deposits are called amyloid plaques, and they are known to play a significant role in the pathogenesis of the diseases grouped as amyloidosis (some of which are listed in table 1). The plaques originate from normally soluble monomeric proteins which misfold, aggregate and assemble into insoluble fibrillar structures. The fibrils adopt a characteristic cross- $\beta$  sheet structure, where the individual  $\beta$ -sheets run perpendicular to the fibril axis (Figure 1). The fibrils are unbranched and can reach lengths of several  $\mu\text{m}$ , with a diameter of approximately 7-12 nm (Chiti & Dobson, 2017; Sunde et al., 1997). Formation of amyloid structures can be monitored directly by transmission electron microscopy or indirectly via dyes, such as Congo red or Thioflavin T (ThT) where the intensity of these dyes is generally considered to correspond to the amount of amyloid material present in the sample (Malmos et al., 2017; Qin et al., 2017).

**Figure 1.** Typical architecture of a cross- $\beta$  structure. **a)** Side view of fibril structure composed of stacked  $\beta$ -sheets aligned perpendicular to the fibril axis. **b)** top view of a). **c)** Diffraction pattern of a typical amyloid fibril, where meridian  $\sim 4.7$  Å corresponds to the regular spacing between  $\beta$ -strands within a  $\beta$ -sheet, and equator  $\sim 10$  Å indicates the periodicity of  $\beta$ -sheets stacked on top of each other. ### 1.3 Alzheimer's disease

Alzheimer's disease (AD) is a neurodegenerative disease characterized by the accumulation of proteinaceous aggregates in the brain. It is the most common form of dementia, with approximately 55 million cases worldwide (World Health Organization [WHO], 2023). The disease was first described by the German pathologist Alois Alzheimer in 1907 (Alzheimer, 1907). This article was later summarized and translated to English (Alzheimer et al., 1995). Dr. Alzheimer presented a case report of a woman who in her early 50's started to show symptoms of dementia. After her death in 1906 (aged 55). Dr. Alzheimer performed the post-mortem analysis of an atrophic brain with previously undescribed neuropathological features and deposits. The deposits are today called amyloid plaques and neurofibrillary tangles (NFTs), and are typical features that are associated with AD (Alzheimer et al., 1995). NFTs consist of hyperphosphorylated aggregates of the microtubule associated Tau proteins, which are assembled into strands and deposited within nerve cells (Zempel & Mandelkow, 2014). The amyloid plaques are instead primarily built up from the amyloid- $\beta$  ( $A\beta$ ) peptides and are mainly encountered extracellularly (Y. Zhang et al., 2023), ( $A\beta$  is further described in section 1.5).

A typical clinical presentation of AD starts with an asymptomatic period, where initial deposition of  $A\beta$  and NFTs starts the neuronal disruption, although the patient is not experiencing any symptoms. This period may last for many years or even decades (Jessen et al., 2022; Price & Morris, 1999). The first symptom of the disease is often mild memory loss, and at this stage are areas such as entorhinal cortex, hippocampus, cingulate cortex and parietotemporal cortex affected (Herholz et al., 2002; Hyman et al., 1984; Scheff & Price, 2001). As the disease progresses, language, reasoning and social behavior become affected. At a late stage, many brain areas do not function normally, and the progression of synaptic loss is highly correlated with the disease severity. The outcome is always fatal, even though the cause of death is usually not the disease itself, but rather secondary complications such as pneumonia, malnutrition, or heart failure (Alzheimers Association, 2023; Kukull et al., 1994; Terry et al., 1991).

The risk of developing AD increases with age, and AD is most common in people over the age of 65 (Reitz et al., 2011). As global life expectancy increases (WHO, 2024), it is expected that AD prevalence will increase. The disease does not only cause a lot of individual suffering, but also a great economic challenge for society. In 2019, the global cost of AD was estimated to be approximately 1.3 billion US \$ (Wimo et al., 2023), and this number will increase in relation with the increasing number of patients.

The disease is divided into two subtypes: familial and sporadic Alzheimer's disease (fAD and sAD, respectively), where sAD is responsible for more than 95% of all cases (Chakrabarti et al., 2015; Reitz et al., 2011; van der Flier & Scheltens, 2005). The onset of the fAD usually occurs at an earlier age (age < 65 years), than sAD and numerous mutations in genes such as the amyloid precursor protein (APP), presenilin 1 (PSEN1), and presenilin 2 (PSEN2) have been linked to fAD (Cai et al., 2015; Kelleher & Shen, 2017; Li et al., 2019). The mutations typical for fAD often result in increased  $A\beta$  production and affect the length of the peptides produced, often increasing the levels of more toxic and aggregation-prone  $A\beta$  variants. Unlike fAD, sAD does not follow a clear inheritance pattern. Instead sAD is thought to be influenced by a complex interplay of genetic, environmental and lifestyle factors, such as air pollutions (PM<sub>2.5</sub>, NO<sub>2</sub>, NO) (Wilker et al., 2023) pesticides (Yan et al., 2016), metals (Babic Leko et al., 2023; Bakulski et al., 2020), cigarette smoking (Cataldo et al., 2010; Wallin et al., 2017), diet (Agarwal et al., 2023),

exercise (Meng et al., 2020), sleep (Sabia et al., 2021), and traumatic brain injury (TBI) (Mielke et al., 2022). Although the connections are not yet fully understood, several genetic risk factors have also been implicated in sAD and the primary genetic risk factor that has been identified is the apolipoprotein  $\epsilon 4$  allele. It is, however, essential to note that carrying the apolipoprotein  $\epsilon 4$  allele does not guarantee that an individual will develop the disease (further described in section 1.6). Mutations in genes involved in various biological processes such as the immune system, endocytosis and lipid transport may also be associated with the disease (De Roeck et al., 2019; Foster et al., 2019; Guerreiro & Hardy, 2014).

## **1.4 Molecular aspects of Alzheimer's disease**

Understanding Alzheimer's disease is a major challenge in current research and healthcare. During many decades of research, considerable progress has been made regarding the clarification of biochemical and molecular mechanisms involved in the progression of AD, some of which are presented below.

### **1.4.1 The cholinergic hypothesis**

An early hypothesis presented in the late 1970's and early 1980's to explain AD pathogenesis was the *cholinergic hypothesis* (Bartus et al., 1982; Davies & Maloney, 1976). The hypothesis suggests that loss of the cholinergic neurons and decreased levels of acetylcholine (ACh) have a central role in the cognitive deficits observed in AD. This was based on observations of reduced cholinergic activity in the brains of individuals with AD, in combination with the clinical efficacy of acetylcholinesterase inhibitors. Acetylcholinesterase inhibitors increase the ACh levels present and can (temporarily) improve function in the cognitive system of some AD patients (Nordberg & Svensson, 1998). Today it is widely accepted that the cholinergic hypothesis is not the sole explanation for the cognitive decline in AD, although acetylcholinesterase inhibitors are currently used for symptom relief in AD (Vaz & Silvestre, 2020).

### **1.4.2 Amyloid cascade hypothesis**

In the early 1990's Hardy and Higgins (1992) first presented the *amyloid cascade hypothesis*, which suggests that the abnormal accumulation of  $A\beta$  in the brain is the initial cause of AD. It suggests that the peptide accumulation initiates a cascade of events that contributes to the progression of the disease. This was supported by the fact that individuals with Trisomy 21 (i.e. Down's syndrome) often develop AD at an early age, explained by the presence of an extra copy of the gene encoding  $A\beta$  precursor protein, located on chromosome 21 (Fortea et al., 2021; Strydom et al., 2018). Additionally, many mutations associated with fAD are associated with alterations in  $A\beta$  production, especially upregulation or shifting the production towards the more toxic peptide species (Selkoe, 2008).

There is currently an ongoing debate regarding the relevance of this hypothesis as it has been shown that  $A\beta$  content is not always correlated with the development and severity of AD and individuals may have a significant number of amyloid plaques in the brain, without showing symptoms of the disease (Aizenstein et al., 2008; Delaere et al., 1990; Dickson et al., 1992). Besides that, another argument against the hypothesis is the fact that therapies developed to target amyloid production, aggregation or clearance have failed to show significant effects (Ricciarelli & Fedele, 2017). The amyloid cascade

hypothesis might not be the sole or complete explanation for the pathogenesis of AD, yet there is no doubt that A $\beta$  is linked to the disease and that it plays a significant role in AD pathology.

### **1.4.3 Tau hypothesis**

The *tau hypothesis* states that abnormal hyperphosphorylation of Tau results in the formation of paired helical filaments (PHF-tau) and NFTs in AD (Iqbal et al., 2016; Kosik et al., 1986; Mohandas et al., 2009) which are highly toxic to neurons, disrupt microtubule stability, and as a result impair cellular transport, eventually leading to synaptic dysfunction and cell death (Gendreau & Hall, 2013; Kopeikina et al., 2012; Maccioni et al., 2010). The fact that the amount of NFTs generally correlates with the progression of the disease and that mutations in the tau-encoding gene (microtubule-associated protein tau, MAPT) lead to abnormal tau aggregation and neurodegeneration, are two arguments in favor of hypothesis that tau aggregates are the main toxic species in AD.

### **1.4.4 The oligomeric hypothesis**

The oligomeric hypothesis suggests that the smaller, soluble oligomers of A $\beta$  are the most neurotoxic forms and therefore the primary cause of onset and progression of AD. The hypothesis arose during the late 1990s when the amyloid cascade hypothesis started to be questioned, and focus was shifted towards these smaller A $\beta$  aggregates. The oligomers have been shown to interfere with synaptic signaling pathways, disrupt long-term potentiation, interact with cellular membranes and as a result cause leakage. This hypothesis is also supported by the observation that there is a good correlation between the levels of soluble A $\beta$  oligomers, cognitive deficits and synaptic dysfunction (Cline et al., 2018; Ferreira & Klein, 2011).

The oligomeric species are very unstable, and therefore difficult to study. Many protocols are used for the preparation of oligomers *in vitro*, and as a result a lot of variations have been observed. These inconsistencies complicate the studies of oligomers, as their function, structure and toxicity may be largely affected by minor changes in the experimental setup.

### **1.4.5 The metal hypothesis**

The metal hypothesis argues that metal ion dysregulation plays a crucial role in AD. Particularly copper, iron and zinc have been suggested to contribute to AD pathogenesis. In early studies these metal ions showed interaction with the A $\beta$  peptides and were found in elevated levels in amyloid plaques (Lovell et al., 1998; Miller et al., 2006). Metal homeostasis is important, and concentrations of metal ions must be tightly regulated to ensure proper cellular functioning and maintain essential processes such as redox balance and enzymatic activity (Alberts et al., 2008). However, patients with AD often display metal dyshomeostasis, which is considered to contribute to the aggregation of the A $\beta$  peptide. Binding of metal ions can for example induce conformational changes in the peptide that facilitate aggregation. Metal ions are also known to contribute to oxidative stress by generating reactive oxygen species (ROS), which in turn interfere with biological processes, and potentially contribute to the disease. Additionally, metal ions affect A $\beta$  production and the length of the peptide (by modulating APP cleavage) (De Benedictis et al., 2019; Maynard et al., 2005). It is worth noting that although metal dyshomeostasis in AD is widely accepted, it is not known if it is a cause of, or an effect of

the disease. Furthermore, it is not clear if metal ions contribute to the formation of amyloid plaques *in vivo*, or if the ions bind to the already formed plaques. Therefore, the metals may cause secondary effects instead of contributing to the initial disease pathogenesis. In either way, once bound to the plaques, the metal ions may contribute to neuronal damage through ROS formation. There are still many gaps in the metal hypothesis, and it is probably not the sole cause of the disease, however, metal ions likely play an important role in disease progression (Aaseth et al., 2016; Bush, 2013; Bush & Tanzi, 2008; Chen et al., 2023).

#### **1.4.6 Mitochondrial dysfunction and oxidative stress in Alzheimer's disease**

The functionality of the mitochondria has been recognized as a critical factor in AD. The mitochondria are considered the powerhouse of the cell and are essential for energy production, regulation of cellular metabolism, and maintenance of cellular health (Alberts et al., 2008). In AD brains, it has been shown that the mitochondrial dynamics is disturbed, resulting in a disruption of the morphology and functioning of the organelles. Neurons are highly energy-consuming cells, and mitochondrial dysfunction leads to decreased ATP production. Energy deficits may impair several cellular functions, including synaptic activity and plasticity, both of which are crucial processes for memory formation and cognitive functions (Cunnane et al., 2020). Mitochondria are also vital for neurotransmitter release in the presynaptic terminal, where they supply ATP, and also regulate intracellular calcium levels. In AD, this regulation is often disrupted, leading to elevated calcium levels which results in altered neuronal activity and may result in activation of cell death pathways (Guan et al., 2021). In addition, a dysfunctional mitochondrion may produce ROS and cause oxidative stress as a result of disturbances in the electron transport chain (Guo et al., 2013).

Oxidative stress refers to an imbalance between the production of ROS and the ability to detoxify these harmful compounds and repair the resulting damage. Under normal physiological conditions, a balance between ROS production and neutralizing antioxidative processes allows the cell to function normally. An overproduction of ROS disturbs this balance and leads to oxidative stress in the cell. ROS are natural byproducts of the cellular metabolism, particularly within the mitochondria during aerobic respiration but are also produced by macrophages and neutrophils in the immune system (Checa & Aran, 2020). Increased ROS levels may damage cellular components, including lipids, proteins and DNA which could impair cellular functions, induce apoptosis or contribute to the pathogenesis of various diseases (Shields et al., 2021). A wide range of diseases have been associated with oxidative stress, including cardiovascular diseases, diabetes, cancer, and aging, but also neurodegenerative diseases like PD and AD (Knott et al., 2008; Ray et al., 2012; Reddy et al., 2011; Wang et al., 2009). The mitochondrial dysfunctions often observed in AD patients are likely part of a vicious cycle, where dysfunctional mitochondria-induced oxidative stress causes even further damage which may damage additional mitochondria.

Both A $\beta$  and hyperphosphorylated Tau have been shown to interact with and affect the mitochondria negatively. A $\beta$  can interfere with the electron transport chain, thereby further increasing ROS production and reducing the efficiency of ATP production (Bobba et al., 2013; Spuch et al., 2012). Hyperphosphorylated tau, on the other hand, has been shown to disrupt the distribution of mitochondria inside the cell, which naturally affects the cell function (Isei et al., 2024). The A $\beta$  peptides can induce ROS by themselves, and disrupt cellular membranes caused by lipid peroxidation (Cenini et al.,

2010; Cheignon et al., 2018; Harris et al., 1995). Moreover, A $\beta$  peptides can induce ROS also through interactions with metal ions (extensively described in section 1.7).

Increased oxidative stress furthermore increases the risk of mutations in the mitochondrial DNA, which further results in defective mitochondrial proteins and contributes to additional mitochondrial dysfunction and the pathogenesis of AD (Druzhyina et al., 2008).

### 1.4.7 Neuroinflammation in Alzheimer's disease

Both A $\beta$  aggregates and NFTs are thought to be able to activate an inflammatory response in the brain by activating glial cells (primarily microglia and astrocytes) (Hickman et al., 2018; Kim & Choi, 2015). Activated microglia release pro-inflammatory cytokines and chemokines, such as Interleukin-1, Interleukin-6 and tumor necrosis factor alpha, which in turn amplifies the inflammatory response by recruiting more immune cells (Gao et al., 2023). A chronic neuroinflammation may give rise to neuronal damage and further contributes to cognitive decline, and many inflammatory processes also lead to oxidative stress (Adamu et al., 2024; Mittal et al., 2014; W. Zhang et al., 2023).

AD is a complex and multifactorial disease, and the pathology of the disease is likely an interplay of multiple factors and pathological processes. The hypotheses presented in this section all contribute with different aspects of pathophysiology, adding pieces to the puzzle of AD (Figure 2).

**Figure 2.** Simplified scheme of factors contributing to the progression of Alzheimer's disease. These (and many other) elements interact in a complex network, producing neuronal damage, synaptic loss, and cognitive decline.

## 1.5 Amyloid $\beta$

The 36-43 residues long amphipathic A $\beta$  peptide is produced by enzymatic cleavage of the amyloid precursor protein, APP (Mawuenyega et al., 2013). A $\beta$  was first described as a major component of the amyloid plaques found in the brains of AD patients in 1984 (Glenner & Wong, 1984). The A $\beta$  peptide exists in different forms in humans, but also across various animal species. The variation in amino acid sequence affects how prone the peptides are to aggregate and thus, their possible contribution to AD pathology. In

humans, the A $\beta$ <sub>1-40</sub> variant is the most common form of the peptide in the brain, whereas the A $\beta$ <sub>1-42</sub> variant (Figure 3) shows a greater propensity for aggregation and is therefore considered to be more toxic (Mori et al., 1992; Naslund et al., 1994). In murine species, three amino acids are substituted, compared to human wild type A $\beta$ , i.e. R5G, Y10P, and H13R. Additionally, rodent A $\beta$  is also known to be less aggregation-prone than human A $\beta$  (Xu et al., 2015). The A $\beta$  peptide exists in many other species where there are variations in sequence, propensity to aggregate and structure. Although many species can display human-like amyloid aggregates, only few species are showing AD-like symptoms (Chen & Zhang, 2022; Walker & Jucker, 2017).

Although it is mostly associated with the pathogenesis of AD, it is important to note that A $\beta$  is also present in healthy brains. It has been suggested to be involved in cell survival, memory formation, neuronal communication, and plasticity (Puzzo et al., 2015; Soucek et al., 2003). Studies have shown that knocking out the gene and enzymes involved in A $\beta$  production leads to a significant reduction in A $\beta$ , but also results in various neurological deficits and developmental problems (Dawson et al., 1999; Plant et al., 2003; Zheng et al., 1995). Thus, A $\beta$  seems to have an important biological role in the brain, but the details are unclear.

In an aqueous solution at physiological pH values, the monomeric A $\beta$  peptide is negatively charged, intrinsically disordered and adopting a random coil conformation. In a membrane or membrane-mimicking environment, the peptide adopts an  $\alpha$ -helical secondary structure. In a detergent micelle, the C-terminal and central part of the peptide localizes inside, while the N-terminal remains unstructured outside the micelle (Tiiman et al., 2016). Upon aggregation, the peptide folds into  $\beta$ -sheets, which enable formation of amyloid fibrils (Rambaran & Serpell, 2008). The N-terminal part of the A $\beta$  peptide contains three histidine residues (H6, H13, H14), where the nitrogen in the imidazole ring can coordinate metal ions. The central and C-terminal segments of the peptide are hydrophobic and may interact with membranes or fold into hairpin conformation, likely required for aggregation (Figure 3) (Abelein et al., 2014). The A $\beta$ <sub>1-42</sub> peptide has two additional hydrophobic residues in the C-terminal (i.e. I41 and A42), making this variant less soluble in aqueous solution than A $\beta$ <sub>1-40</sub>, but also contributing to its aggregation propensity. The presence of these additional hydrophobic amino acids residues alters the molecular structure and, stabilizes the intermolecular interactions which drive aggregation (Sgourakis et al., 2007).

**Figure 3.** Amino acid sequence of A $\beta$ <sub>1-42</sub>. Blue: Histidine residues, mainly uncharged at neutral pH and protonated below pH ~6. Red: acidic, negatively charged residues at neutral pH. Purple: Positively charged residues at neutral pH. Amino acids that can be involved in metal coordination are marked with \* and hydrophobic regions are overlined. Adapted from: (Wärmländer et al., 2019).

### 1.5.1 Generation of A $\beta$

The A $\beta$  peptide is produced by proteolytic cleavage of the amyloid precursor protein (APP) (Nunan & Small, 2000). APP is a transmembrane protein mainly located in the plasma membrane and is primarily expressed in neural tissues (O'Brien & Wong, 2011). The APP gene is in humans located on chromosome 21 (Korenberg et al., 1989; Patterson et al., 1988; Tosh et al., 2021) and is spliced into three variants of different lengths (APP<sub>770</sub>, APP<sub>751</sub> and APP<sub>695</sub>), where the APP<sub>695</sub> is the isoform most commonly found in the

brain (Delport & Hewer, 2022). APP contains a region that encodes for the A $\beta$  peptide, and whether A $\beta$  is produced or not depends on the specific enzymes involved in the enzymatic cleavage of APP (O'Brien & Wong, 2011). Under normal conditions, APP primarily follows the non-amyloidogenic pathway (Figure 4), where alpha ( $\alpha$ )-secretases such as Disintegrin and Metalloprotease 10 (ADAM10) cleave APP within the A $\beta$  fragment, resulting in a soluble amyloid precursor protein-alpha (sAPP $\alpha$ ) fragment of 612 amino acids that is released into the extracellular space (Chasseigneaux & Allinquant, 2012; De Strooper et al., 2010). This, while an 83-residue long carboxyl-terminal fragment alpha (CTF $\alpha$ ) is released intracellularly (Chen et al., 2017). The sAPP $\alpha$  fragment is important in the brain development, involved in the regulation and proliferation of neuronal stem cells (Coronel et al., 2019). It is also thought to have a role in processes such as memory formation and synaptic plasticity in the mature brain (Ishida et al., 1997).

The subsequent cleavage of the CTF $\alpha$  fragment is performed by the gamma ( $\gamma$ )-secretase, a protein complex containing among other subunits also PSEN1 or PSEN2 (De Strooper et al., 2012). This cleavage results in the APP intracellular C-terminal domain (AICD) and the small P3 peptide (~3 kDa). The exact roles of these intracellularly released fragments are not yet elucidated. As the P3 peptide seems to be rapidly degraded, it suggests that P3 has no significant pathological or even biological function (Zhang et al., 2011).

In the amyloidogenic pathway, APP is instead cleaved by beta ( $\beta$ )-secretase which cuts APP and leaves the A $\beta$  fragment complete and attached to the CTF $\beta$  fragment. One of the most common  $\beta$ -secretases are the Beta-Site APP cleaving enzyme 1 (BACE1), which belongs to the pepsin family of proteases and requires acidic conditions for optimal enzymatic activity (Cole & Vassar, 2007; Haass et al., 1993). The  $\gamma$ -secretase then cleaves the CTF $\beta$  fragment, leaving the AICD and an A $\beta$  monomer (Figure 4). The main difference between the two pathways is that the  $\alpha$ -secretase in the non-amyloidogenic pathway cuts within the A $\beta$  sequence, hindering its production, while the  $\beta$ -secretase in the amyloidogenic pathway cleaves outside the A $\beta$  site, making the formation of A $\beta$  peptides possible (Nathalie & Jean-Noel, 2008).

The native role of APP is currently under discussion, but the evolutionary conservation of its gene family suggests that it serves an important function (Tharp & Sarkar, 2013; Zheng & Koo, 2011). APP is known to be involved in cell adhesion, neuronal guidance, synapse formation, to act as cell surface receptor, regulate synapse formation, and influence cell division (Ejaz et al., 2020; Nhan et al., 2015). Its importance is further confirmed by the negative effects observed in APP knockout mice (Mazinani et al., 2020; Senechal et al., 2008; Zheng et al., 1995). Additionally, APP have shown to bind Cu ions and are suggested to be implicated in iron metabolism (Wild et al., 2017).

Interestingly, it has been shown that the APP cleavage is not limited to the plasma membrane. APP can be transported into early endosomes by endocytosis, where  $\beta$ -secretase (especially BACE1) and  $\gamma$ -secretase, but less  $\alpha$ -secretase is present. The lower pH in the early endosomes (approximately pH 6.5 (Hu et al., 2015)) promotes BACE1 cleavage, resulting in increased A $\beta$  production. It has therefore been suggested that toxic A $\beta$  may be produced intracellularly and then transported to the extracellular space (Fourriere et al., 2022; Iizuka et al., 1996; Skovronsky et al., 1998; Turner et al., 1996).

**Figure 4.** Proteolytic cleavage of the APP by  $\alpha$ -,  $\beta$ - or  $\gamma$ -secretase directs the protein into either the non-amyloidogenic or the amyloidogenic pathway. Adapted with permission from (Hampel et al., 2021).

### 1.5.2 Aggregation of A $\beta$

The aggregation of A $\beta$  is a complex and critical process in the pathogenesis of AD. The monomeric A $\beta$  peptides undergo a series of structural changes and interactions which lead to the formation of aggregates and plaques in the brain.

To initiate aggregation, the A $\beta$  peptides must exceed the critical aggregation concentration (CAC). While the CAC varies depending on the surrounding environment, it is estimated to be around 100 nM for A $\beta_{1-40}$  under physiological conditions, and even less for the more aggregation-prone A $\beta_{1-42}$  peptide (Brannstrom et al., 2014; Iljina et al., 2016).

The aggregation process can be divided into three stages (Figure 6). It begins with the lag phase, where monomers typically exist in a disordered state. As the concentration of A $\beta$  peptides increases, some monomers undergo conformational changes and begin to associate with each other, forming small aggregates commonly known as oligomers during a process called primary nucleation. Once the critical threshold is reached, the aggregation process enters the transition into a rapid growth phase, called the elongation phase. Here, larger aggregates and fibrils are formed. During this phase, A $\beta$  monomers are primarily added to existing fibril ends, leading to their elongation and growth. Finally, the aggregation process reaches the stationary phase, where a stable concentration of A $\beta$  aggregates is reached. Although some fibrils may continue to grow, there will likely also be fragmentation of already formed structures and so-called secondary nucleation, resulting in a largely consistent aggregate concentration.

As mentioned in section 1.2.2.1, ThT fluorescence is a useful tool for monitoring the amyloid formation in a sample. ThT is a benzothiazole dye that contains a dimethylated benzothiazole ring connected to a dimethylamino benzyl ring via a single carbon-carbon bond (Figure 5). The single carbon-carbon bond makes rotation of the two rings possible which causes quenching of the fluorescence in unbound state. Upon binding to amyloid material, the free rotation is hindered and as a result the quenching is reduced.

This results in a great increase in fluorescence intensity. Therefore, the measured ThT fluorescence intensity roughly corresponds to the amount of amyloid material present in the sample (Biancalana & Koide, 2010; Malmos et al., 2017; Qin et al., 2017). The intensities can be plotted against time and produce a sigmoidal curve from which parameters such as lag time, growth rate and half time for aggregation can be determined (Figure 6). One limitation of the ThT dye is that aggregation of 50-70 monomers is required for the fluorescence to increase. That means that other techniques are required to monitor the initial aggregation steps (Tiiman et al., 2015).

**Figure 5.** Chemical structure of Thioflavin T (ThT). A dimethylated benzothiazole ring connected to a dimethylamino benzyl ring by a single bond (denoted with arrows) which allows free rotation. Upon binding to amyloid material, the free rotation is hindered, and fluorescence can be detected.

The aggregation process is very sensitive to environmental conditions and factors like pH, temperature and presence of metal ions or other small molecules may have a large impact on the aggregation process, influencing both the rate of aggregation and the structural characteristics of the resulting aggregates. The different conditions may alter the balance between different aggregation steps, potentially affecting the stability and toxicity of the aggregates. For example, metal ions such as zinc (II) and copper (II) have been shown to be able to accelerate the aggregation, and variations in pH changes the intrinsic charge of the peptide. This sensitivity makes studies of A $\beta$  peptides complicated and explains why large variations can be observed in similar studies performed by different authors.

**Figure 6.** Aggregation kinetics of A $\beta$  peptides. (A) shows a typical sigmoidal curve obtained from *in vitro* experiments, where the aggregation has been monitored by following the change in ThT fluorescence. (B) processes that takes places during the peptide aggregation. Adapted with permission from (Thacker et al., 2023) and (Kumar & Walter, 2011)

### **1.5.3 Structure of A $\beta$ aggregates**

The aggregation of A $\beta$  peptides is central to the pathology of AD and as previously discussed, the monomeric A $\beta$  peptide is soluble and typically adopts a random coil in aqueous solution and alpha helical structure in a membrane or membrane mimetic environment. The monomeric peptide does not exhibit significant toxicity on its own, although its interaction with other cellular components is suggested to be able to exacerbate pathological conditions (Tamagno et al., 2018). Upon initiation of aggregation, the monomers go through a conformational change, taking on a  $\beta$ -sheet structure which allows them to interact and form insoluble fibrils, characteristic of amyloid plaques. According to the amyloid cascade hypothesis, the aggregation of A $\beta$  was causally linked to explain the pathogenesis of AD and this was initially supported by studies of brain tissues (Mann et al., 1985). However, a few years later the hypothesis started to be debated (Kepp et al., 2023). Researchers observed that the number of amyloid plaques in the brain of AD patients did not consistently correlate with severity of the disease. Some individuals with significant amyloid plaque deposits exhibited only mild symptoms or even normal cognitive function (Ricciarelli & Fedele, 2017). The focus was then shifted to the pre-fibrillar states, as the levels of soluble A $\beta$  aggregates in the CNS of AD patients seemed to correlate better with the pathology (Viola & Klein, 2015). The pre-fibrillar state ranges from dimers to aggregates of hundreds of peptides, i.e. oligomers to protofibrils (Khaled et al., 2023).

#### **1.5.3.1 A $\beta$ oligomers**

A $\beta$  oligomers are small, prefibrillar, soluble aggregates that are currently considered to be the main toxic species in AD pathology (Cline et al., 2018; Lee et al., 2017; Walsh & Selkoe, 2004). Although they have been extensively studied for decades, no clear definition of their size has been stated, but it is common that dimers to dodecamers are considered oligomers, while larger and more fibrillar-like aggregates are called protofibrils (Cline et al., 2018; Sakono & Zako, 2010). Due to their instability, the secondary structure of the oligomers is not completely understood. They are thought to lack the highly ordered arrangements characteristic for mature fibrils and instead consist of mixed structures of  $\beta$ -sheets and random coil (Bitan et al., 2003; Ono et al., 2009).

Although the toxicity caused by oligomers is widely accepted, it is not yet completely understood how they exert their toxicity. For example, it has been suggested that the oligomers may have prion-like properties, meaning that they can be distributed between cells (Walker et al., 2016; Willbold et al., 2021). They are also thought to be able to disrupt cellular membranes, both intra- and extracellularly, thereby weakening membranes and inducing leakage. This may among other effects contribute to the Ca-dysregulation that is known to be associated with AD (Popugaeva et al., 2020; Serra-Batiste et al., 2016). Additionally, A $\beta$  oligomers have been shown to bind to a variety of biomolecules, and thereby affect their natural function (Taniguchi et al., 2022; Wiatrak et al., 2021; Zhao et al., 2008).

#### **1.5.3.2 A $\beta$ fibrils and plaques**

Mature A $\beta$  fibrils are the end product of the fibrillogenic pathway. The fibrils display an elongated morphology which can reach several  $\mu$ m, with a diameter of approximately 7-12 nm (Chiti & Dobson, 2017; Sunde et al., 1997). X-ray diffraction has shown that fibrils are unbranched structures composed of cross- $\beta$  sheets (Figure 1), a structure which many amyloid fibrils have in common (Fandrich, 2012; Sunde et al., 1997). Cross- $\beta$  sheet structures are composed of hydrogen bonded  $\beta$ -strands that are packed perpendicular

to the fibril axis, creating highly ordered, stable aggregates that are resistant to proteolysis (Sabate & Ventura, 2013). The fibrils can aggregate into amyloid plaques, mainly through non-covalent interactions such as hydrogen bonding and hydrophobic interactions between fibrils. The plaques are mainly observed extracellularly (Jankovska et al., 2020). Although mature amyloid plaques are mainly composed of fibrils of the A $\beta$  peptide, many other components are often also found within the plaques. Proteins such as Apolipoprotein E, proteoglycans, lipids and metal ions can also bind to the fibrils and might play a stabilizing role and might contribute to the plaque formation (Liao et al., 2004; McGeer et al., 1994; Stewart & Radford, 2017; Xiong et al., 2019).

## 1.6 Apolipoprotein E

As mentioned in section 1.3, Apolipoprotein E (ApoE) has been shown to be a protein involved in AD. ApoE is a glycoprotein composed of 299 amino acid residues with a molecular mass of ~34kDa. It is involved in the transport and metabolism of lipids and contributes to lipid homeostasis in the body. The protein is encoded by the ApoE gene, located on chromosome 19 (Liu et al., 2013; Moreno-Grau et al., 2018). In CNS ApoE is mainly produced by astrocytes and the production has been shown to increase upon injury to the brain, suggesting its involvement in the repair of the nervous system (Chen et al., 1997) as well as in inflammatory responses in the brain (Lynch et al., 2003; Vitek et al., 2009).

The protein exists in three isoforms (ApoE2, ApoE3 and ApoE4), where ApoE3 is the most common and considered the normal form (Huang & Mahley, 2014). Only a single amino acid residue distinguishes ApoE2 and ApoE4 from ApoE3 (Figure 7). In ApoE2 the arginine at position 158 is exchanged to a cysteine, and in ApoE4 the cysteine at position 112 is exchanged to an arginine (ApoE2: C112 and C158, ApoE3: C112 and R158, ApoE4: R112 and R158).

The protein contains an N-terminal segment (residue 1-191) of mainly amphipathic alpha helices arranged in coiled-coils with the hydrophobic residues arranged in the protein's interior, while the polar, charged and hydrophilic residues are located on the protein surface. The N-terminus can bind to low-density lipoprotein (LDL) receptors and is therefore important for binding of lipoproteins. The C-terminus (residue 216-299) is also composed of amphipathic helices, and it is involved in lipid binding (Raussens et al., 1998; Segrest et al., 1992; Strittmatter et al., 1993; Weisgraber, 1994; Wilson et al., 1991; Yamauchi et al., 2008).

It has been shown that carriers of ApoE- $\epsilon$ 4 allele are more susceptible to both mercury intoxication and at greater risk of developing AD (Corder et al., 1993; Farrer et al., 1997; Godfrey et al., 2003; Kim et al., 2009; Manelli et al., 2007). In contrast, the ApoE- $\epsilon$ 2 isoform is considered "protective" against AD (Li et al., 2020). The underlying reason remain unknown, but as the -SH groups of cysteines are known to bind metals, including Hg (Ajsuvakova et al., 2020; Mesterhazy et al., 2018), it has been suggested that the ApoE protein may be involved in removal of Hg from tissue and that the lacking cysteines in ApoE4 would result in a reduced capacity for metal removal. At the same time, the binding of Hg ions to ApoE proteins has not been studied.

**Figure 7.** Structure of Apolipoprotein E (residues 23-162) showing a predominance of alpha helices. Residues 112 and 158 are marked in red and indicate where the three ApoE variants differ. Structure was determined by X-ray diffraction. PDB ID: 1B68, protein structure is visualized with Chimera version 1.18 (Pettersen et al., 2004).

### 1.6.1 Relevance of Apolipoprotein E in Alzheimer's disease

Genetic analyses have shown that carrying an ApoE  $\epsilon$ 4 allele not only increases the risk of developing AD, but it also lowers the mean age of clinical onset (Bertram et al., 2007; Corder et al., 1993; Genin et al., 2011; Mishra et al., 2018; Rebeck et al., 1993; Roses, 1996). It is estimated that the risk of developing the disease increases 4-fold for heterozygotic carriers of the  $\epsilon$ 4 allele, and up to 12-fold for homozygotic carriers (Mahley & Huang, 2012). Interestingly, carrying the  $\epsilon$ 2 allele seems to have a protective effect and reducing the risk of developing AD (Corder et al., 1994; Li et al., 2020).

Exactly how the ApoE4 gene increases the risk of developing AD is not completely understood. It has been shown that compared to ApoE2 and ApoE3, the degradation and removal of A $\beta$  from the brain are less effective in ApoE4 carriers, and ApoE4 can stabilize the A $\beta$  peptide and to some extent increase the rate of its aggregation (Deane et al., 2008; Ma et al., 1994; Shackleton et al., 2019; Wisniewski et al., 1994). In a mice model, the ApoE4 isoform increased the half-life of A $\beta$  peptides in the brain, and the ApoE4 mice also showed higher levels of amyloid-related gliosis, whereas ApoE3 reduced it (Liu et al., 2017). The ApoE4 isoform also increased A $\beta$  production more than ApoE3 in cell cultures expressing APP (Ye et al., 2005).

Besides the interactions between the ApoE protein and A $\beta$  peptide, ApoE4 is also associated with an increased inflammatory response in the brain, and is able to increase the inflammatory response by affecting the activation of microglial cells (Fernandez et al., 2019; Ferrari-Souza et al., 2023; Lee et al., 2023).

The blood brain barrier (BBB) is a highly selective semi-permeable membrane between the blood and the brain and controls trafficking of compounds into the brain, and it prevents entries of potentially toxic molecules and pathogens. The ApoE4 protein has been associated with a reduced integrity of the BBB, which may have a crucial effect

and result in a disrupted brain environment (Halliday et al., 2016; Jackson et al., 2022). The ApoE4 protein has also been shown to be less effective in lipid transport, which could negatively affect neuronal survival and plasticity (Yang et al., 2023).

## **1.7 Metal ions in Alzheimer's disease**

More than 80% of the periodic table of elements consists of metals, many of which are essential for biological processes and crucial for the normal functioning of the human body. Metals such as iron (Fe), calcium (Ca), zinc (Zn), copper (Cu), manganese (Mn) and magnesium (Mg), are involved in enzymatic functions, transport of oxygen, DNA synthesis, regulation of oxidative stress and neuronal signaling (Majorek et al., 2024). As many physiological processes are dependent on metals, their proper regulation and homeostasis are crucial for health as both excess and deficiencies may lead to a variety of disorders (Wang & Zhang, 2015). Metals can directly affect proteins by breaking salt bridges, causing oxidative stress, inducing protein denaturation, and in the case of proteinopathies like AD, affect the aggregation processes. In AD and several other proteinopathies, metal dyshomeostasis is implicated and thought to be involved in the disease's progression, by inducing accumulation of peptides, increasing ROS production and impairing of biomolecular functions (Chen et al., 2023; Das et al., 2021). Already in the 1990's researchers showed that Zn(II) ions could affect A $\beta$  aggregation (Bush et al., 1994), and that AD brains display abnormal metal concentrations (Babic Leko et al., 2023; Wang et al., 2020). In addition, amyloid plaques have shown to contain elevated levels of Zn, Cu and Fe (~mM concentration) (Beauchemin & Kisilevsky, 1998; Faller & Hureau, 2009; Lovell et al., 1998; Miller et al., 2006). The disrupted metal homeostasis in AD is a commonly recognized problem, however, the details are not yet fully understood. The published literature about this subject further highlights the complexity, as publications in many cases show contradictory results with both increased and decreased concentrations of metal ions in AD brains (Babic Leko et al., 2023; Brewer, 2014; Cicero et al., 2017; Lovell et al., 1998; Squitti et al., 2014).

Iron, copper and to some extent other transition metals such as manganese and nickel can participate in Fenton-type reactions where reactive hydroxyl radicals are formed by interaction between metal ions and hydrogen peroxide in redox reactions. The reactions happen when the metal ions recycle between different redox states, react with hydrogen peroxide, and create hydroxyl radicals which are highly reactive and contribute to oxidative stress (Gao et al., 2022; Lloyd & Phillips, 1999)

It is widely accepted that the metal homeostasis is disrupted in AD patients, but it is not yet elucidated whether the changes are a cause or an effect (or both) of the underlying pathology. Although it is not thought to be the sole cause of the disease, abnormal metal metabolism and homeostasis is believed to contribute to the disease's progression by, among other things, affecting the aggregation of AD-related proteins and contributing to oxidative stress and neurotoxicity (Babic Leko et al., 2023; Huat et al., 2019; Islam et al., 2022).

### **1.7.1 Metal binding properties of A $\beta$ peptides**

Metal binding to the A $\beta$  peptide has been extensively studied for many years and the main focus has been on the most biologically relevant metals such as Cu, Ca, Zn and Fe, especially since these metals were found in elevated concentrations in amyloid plaques (Beauchemin & Kisilevsky, 1998; Lovell et al., 1998; Miller et al., 2006). The binding of metals ions to A $\beta$  influences the net charge of the peptide, which affects the stability and

conformations of peptide regions and may destabilize the secondary structures in the peptide. This destabilization may induce a shift towards more stable conformations such as  $\beta$ -sheets, which in turn could facilitate the aggregation of peptides into amyloid fibrils. Metal ions have *in vitro* been shown to stabilize soluble oligomers, which could enhance their neurotoxicity if it would happen *in vivo* (Gonzalez Diaz et al., 2024; Ryan et al., 2015; Williams et al., 2016).

Interestingly, the metal: peptide ratio plays an important role and affects the rate of aggregation and morphology of aggregates. For example, the sub-equimolar concentrations of Cu(II) ions push the aggregation towards ThT-active, larger aggregates, whereas supra-equimolar concentrations promote formation of smaller oligomers and amorphous aggregates (Jin et al., 2011; Pedersen et al., 2011; D. P. Smith et al., 2007).

The A $\beta$  peptide lacks cysteine residues (Figure 3), which are typical metal binding residues, however, the A $\beta$  N-terminus contains aspartic acids and glutamic acids (D1, E3, D7 and E11). These residues are negatively charged and are likely to bind positively charged metal ions. Additionally, the peptide contains three histidine residues (H6, H13 and H14) which through their imidazole ring can contribute to the coordination of metal ions under physiological conditions. Histidine residues have a pKa of  $\sim$ 6, which makes their metal binding properties sensitive to pH variations.

Metal ions such as Ni(II), Cu(II), Pb(IV), Zn (II) have been shown to bind at specific sites on the A $\beta$  peptide. This binding occurs in the N-terminal region by involving the His residues as binding ligands. The binding of metals to the A $\beta$  peptide can also be non-specific, as in the case of uranyl, Mn(II) and Pb(II) ions. In these cases, it is proposed that the interactions occur via non-specific electrostatic interactions between negatively charged A $\beta$  residues and the positively charged metal ions (Danielsson et al., 2007; Ghalebani et al., 2012; Wallin et al., 2016; Wallin et al., 2017). Copper is an essential trace element in the human body with several important roles. It is crucial for enzyme function, iron metabolism, the immune response and antioxidant defense (Council, 2000). In the brain and related neurological systems, Cu is a cofactor in several enzymes that are critical in production of neurotransmitters, in the electron transport chain, development and differentiation of neuronal cells and in antioxidant defense (D'Ambrosi & Rossi, 2015; Opazo et al., 2014; Zhiwu Zhu, 2000). The distribution of Cu ions varies in the brain, and areas such as hippocampus, cerebellum, subventricular zone and substantia nigra which are important for memory, motor control, neuronal generation and cognitive functions, have shown abnormal levels of Cu in AD patients (Bagheri et al., 2017; Fu et al., 2015; Magaki et al., 2007; Suryana et al., 2024). Gaier et al. (2013) explained that the levels of copper in synapses can change rapidly, as a result of neuronal activity and suggested that Cu is released to the synaptic cleft during neurotransmission. Interestingly, abnormal Cu homeostasis in the synapses has been linked to both Wilson's disease and AD.

Cu is a redox-active metal that is known to participate in Fenton-like reactions, resulting in the formation of ROS, which as previously discussed is likely a key process in AD. It has also been discussed whether Cu ions accelerate or inhibit A $\beta$  aggregation, as contradictory results have been published. Interestingly, it has been suggested that Zn(II) ions are able to compete with Cu(II) ions for A $\beta$  binding, and this effect may attenuate the amount of harmful redox chemistry caused by Cu interactions (D. G. Smith et al., 2007). It seems most likely that the toxicity of A $\beta$ :Cu complexes in cell cultures is higher, as compared to free copper ions (Faller & Hureau, 2009)

The exact role of Cu in neurodegenerative diseases like AD, HD and PD is not yet understood, but the dysregulation indicates that it plays a role in pathology. It is well known that Cu ions are able to bind to A $\beta$  with a high affinity, and although the exact binding affinity ( $K_D$ -values) varies depending on experimental setup and conditions, it is widely accepted that the Cu(II) ions bind to A $\beta$  with a  $K_D$  value up to 0.1-1 nM (Alies et al., 2013; Conte-Daban et al., 2017; Young et al., 2014).

Metal binding to peptides and proteins can be studied by taking advantage of the intrinsic fluorescence in the aromatic amino acids, i.e. tyrosine, tryptophan and phenylalanine. The A $\beta$  peptide contains one tyrosine residue (Y10), which is located in the N-terminus, in close proximity to the histidine residues at position 6,13 and 14. A decrease in fluorescence upon titration with a metal ion can therefore be assumed to reflect metal binding to the protein, resulting in quenching of the intrinsic fluorescence. Plotting the loss of intrinsic fluorescence against the concentration of added metal gives a binding curve, which can be fitted to e.g. the Morrison equation and an apparent binding affinity ( $K_D$ -value) can be obtained (Kuzmic, 2015). The A $\beta$  peptide also contains three phenylalanine residues, but as the intrinsic fluorescence from these residues is very weak it can be considered negligible in the presence of tyrosine or tryptophan residues.

### 1.7.2 ATCUN-motif

The amino terminal Cu(II)- and Ni(II) binding (ATCUN) motif is a metal binding site, located in the N-terminus of many proteins. It requires a histidine residue at third position. The ATCUN complex consists of a four-nitrogen square-planar coordination mode, with a bound metal ion located in the center. One nitrogen atom is provided by the N-terminal amine, two from the protein backbone peptide bonds and one from the imidazole ring of the histidine residue (Maiti et al., 2020; Sankaramakrishnan et al., 2005).

Interestingly, truncated versions of the A $\beta$  peptide have been found in amyloid plaques, especially A $\beta$ <sub>4-42</sub>, but also A $\beta$ <sub>11-x</sub>, both in patients with AD and in people with trisomy 21 (Liu et al., 2006; Masters et al., 1985; Portelius et al., 2010).

As the A $\beta$  peptide contains histidine residues at position 6, 13 and 14 (Figure 3), truncation into A $\beta$ <sub>4-42</sub> and A $\beta$ <sub>11-x</sub> puts a histidine residue in position three, forming ATCUN-motifs. The truncated A $\beta$  peptides have been shown to bind Cu(II) ions several orders of magnitude stronger than the A $\beta$ <sub>1-40/42</sub> peptide (Barritt & Viles, 2015; Mital et al., 2015), potentially explaining the increased metal content that have been found within amyloid plaques.

### 1.7.3 Dityrosine formation

Dityrosine is a dimeric form of the amino acid tyrosine and occurs when the two amino acids are linked together by a covalent bond between their aromatic rings. Dityrosine can be formed through both enzymatic and non-enzymatic processes, where in the latter case free radicals cause the oxidation of the tyrosine residue. A reactive tyrosyl radical is formed when the hydrogen of the hydroxyl group is removed. This process typically occurs under conditions of oxidative stress, where ROS can induce oxidation of tyrosine residues. Dityrosine crosslinks stabilize the structure of proteins/peptides. Although high levels of dityrosine often indicates oxidative stress and can act as a marker for some biochemical processes and pathological conditions, formation of dityrosine is in some processes thought to be required for proper biological function (Maina et al., 2023). The formation of dityrosine can be monitored *in vitro*, as it emits fluorescence around 350 nm (excited at 315 nm) (Radomska & Wolszczak, 2022).

In the case of A $\beta$ , the peptide contains one tyrosine residue at position 10 (Y10), which can participate in dityrosine formation. Cross-linking of A $\beta$  peptides promotes the formation of aggregates and these will be more resistant to degradation and potentially making normally soluble aggregates insoluble. Dityrosine-linked A $\beta$  peptides have also been shown to be present in amyloid plaques in human AD brain and CSF (Al-Hilaly et al., 2013). Barnham et al. (2004) concluded that in oligomers formed mainly from A $\beta$  peptides where the Y10 residue were exchanged for an alanine (Y10A), showed less toxicity compared to the oligomers of WT peptide. It was therefore suggested that the toxicity of oligomers might be dependent on the cross-linking of Y10 residues. This conclusion is further supported by the fact that murine A $\beta$ , which lacks the tyrosine residue at position 10 (Y10P) generally has less A $\beta$  deposits in their brains.

#### **1.7.4 Interactions of A $\beta$ peptides with non-essential metals**

It has been shown that some non-biologically essential metals are able to accumulate in the brain and contribute to neurotoxicity (Carmona et al., 2021; Ijomone et al., 2020). Understanding the interactions between AD related proteins and metals that are prevalent in industrial and environmental settings such as nickel (Ni), mercury (Hg) and uranium (U) is important, as they may affect the disease progression.

The role of metal ions in AD has been discussed for decades, and as repeatedly mentioned in this thesis, it is still far from elucidated. Therefore, it is important to continue the studies to, if possible, reach a consensus if and how metals are involved in AD pathogenesis.

##### **1.7.4.1 Mercury**

Mercury is a chemical element with the atomic number 80. It occurs in three forms: elemental/metallic (Hg), inorganic (including Hg(I), which typically occurs as diatomic Hg<sub>2</sub><sup>2+</sup> and Hg(II)) and organic (such as methyl- or ethyl mercury, CH<sub>3</sub>Hg<sup>+</sup> and C<sub>2</sub>H<sub>5</sub>Hg<sup>+</sup> respectively). Humans are primarily exposed to Hg from industrial sources and through consumption of seafood. In 2021, the World Health Organization (WHO) placed mercury on the top ten list of “chemicals of major public health concern” and according to the Global Mercury Assessment 2018, the atmospheric Hg increased by 20% between 2010 and 2015, indicating a growing problem (UNEP, 2019; WHO, 2021).

It is well known that Hg is a toxic metal with a wide range of adverse health effects, affecting organs such as the lungs, kidneys, brain and nervous system (Arrifano et al., 2018; Bernhoft, 2012; Rice et al., 2014). Methyl mercury and mercury vapor are especially toxic as they can cross membranes, including the BBB. They are also able to accumulate in the brain and disrupt cellular functions and components through the generation of ROS and oxidative stress, inhibit enzyme function, disrupt Ca homeostasis and as a result interfere with the release of neurotransmitters (Carvalho et al., 2019; Farina et al., 2013; Kerper et al., 1992; Paduraru et al., 2022; Roos et al., 2012). The neurotoxicity of organic mercury such as MeHg is not completely understood. However, important targets for MeHg are sulfhydryl groups, which are present in larger proteins but also in the amino acid cysteine. By modifying the state of the SH-groups, the protein function may become perturbed (Farina et al., 2013).

##### **1.7.4.2 Nickel**

Nickel is a ferromagnetic metal that occurs naturally in the earth's crust in many minerals. It is a common metal in the industrialized world and is used mainly in Ni-Cd batteries, stainless steel and coins. Ni is not an essential metal in humans, although it

seems to be essential for some bacteria and plants (Eskew et al., 1983; Fischer et al., 2016). Nickel can be toxic for humans and may affect the cardiovascular system, have dermatological effects and be neurotoxic. The metal can reach the brain via the olfactory neurons in rats, and thereby circumvent the BBB (Henriksson et al., 1997). It contributes to neurotoxicity through ROS formation, inflammation and mitochondrial dysfunction. It also disrupts neurotransmitter systems, negatively affecting synaptic transmission and plasticity (He et al., 2011; Ijomone, 2021; Marchetti, 2014). One study showed that mice brains exposed to Ni nanoparticles exposed higher concentrations of both A $\beta$ <sub>40</sub> and A $\beta$ <sub>42</sub> than the controls (Kim et al., 2012). Although Ni is not the metal of primary focus in AD, it is a metal commonly occurring in the environment and as a result, many people are exposed and its potential contribution to neurodegenerative processes should not be overlooked.

#### **1.7.4.3 Uranium**

Uranium is a metal with atomic number 92. It occurs in several isotopes, with uranium 238 being the most common. Depending on the chemical form, the toxicity of uranium varies. For example, natural uranium is very weakly radioactive, and its toxicity is primarily exerted through its chemical properties as a heavy metal. Enriched and depleted uranium is most commonly used as fuel in nuclear reactors and in military ammunition, respectively. Uranium is not a very common metal in the environment; however, uranium is a natural component of the earth's crust and activities like mining, volcanoes or industrial work may lead to its release. Therefore, the primary way of uranium exposure is through contaminated soil or water. Uranium mainly affects kidneys and bones, where it can accumulate and cause damage. Its role in neurotoxicity is not very well studied, but it is known to induce ROS, disrupt neurotransmitter release and damage mitochondria. In animal studies, it has been shown that the memory of the uranium exposed animals is affected, and a chronic exposure to uranium can result in depression-like symptoms and sleep disturbances (Lestaevell et al., 2005; Vellingiri, 2023). In this thesis, the metallic oxycation uranyl has been studied, and although the U ion is bound to oxygen, uranium ion is dominant in the molecule. The uranyl ion is soluble in water, and it is the most common form of U found in nature.

## **1.8 Therapeutic strategies for Alzheimer's disease**

AD poses a significant challenge to both healthcare systems and researchers worldwide due to its complex pathology. Despite extensive research, where various aspects and molecular pathways of AD have been targeted, no effective disease-modifying treatment has yet been developed.

Traditionally, AD treatment has focused on symptom management rather than modifying the disease progression (Sheikh et al., 2023). As the cholinergic hypothesis suggest that a decrease in ACh is implicated in the cognitive decline, acetylcholinesterase inhibitors (such as Donepezil, Rivastigmine and Galantamine) have been developed and are used to treat mild to moderate AD by increasing levels of ACh (Annicchiarico et al., 2007). These drugs are often used in combination with NMDA receptor antagonists that can modulate the activity of glutamate which at high concentrations may cause neuronal damage (Hansen et al., 2008; Vaz & Silvestre, 2020).

Since the amyloid cascade hypothesis and the role of APP was proposed and widely accepted in the 1990s (Hardy & Higgins, 1992), a natural target for drug development has been the A $\beta$  peptide. One strategy has been to target the secretases involved in the

proteolytic cleavage of APP, to reduce the amount of A $\beta$  produced. Initially the focus was on inhibiting the main  $\beta$ -secretase (BACE1), but early compounds of BACE1-inhibitors faced challenges with selectivity and exposed an insufficient clinical effect on cognitive and functional decline. In addition, when the amyloid cascade hypothesis started to be debated, many companies shifted their focus towards other targets, resulting in a reduction of BACE inhibitors in clinical trials (Bazzari & Bazzari, 2022; Cummings et al., 2024; Egan et al., 2018). Another strategy is to instead upregulate the  $\alpha$ -secretase (particularly ADAM10) to promote the non-amyloidogenic pathway. This approach showed promising results in a pilot study back in 2014 (Endres et al., 2014) and today two  $\alpha$ -secretase modulator drugs are in phase 2 clinical trials (Cummings et al., 2024; Endres & Deller, 2017).

A problem with targeting the secretases for APP cleavage ( $\alpha$ -, $\beta$ - and  $\gamma$ -secretase) is that they have other important physiological functions and target also other substrates than APP. Therefore, their targeting may have some severe side effects (Hartmann et al., 2002; Hur, 2022).

In recent years, monoclonal antibodies (mAbs) have emerged as a leading and promising strategy in AD treatment as well as in other neurodegenerative diseases such as multiple sclerosis (Freeman & Zephir, 2024). The mAbs are designed to bind A $\beta$  peptides at different stages of aggregation, facilitate their clearance from the brain and thereby might slow down disease progression. In 2021, the mAb Aducanumab was approved for AD treatment in the USA (U.S Food and Drug Administration, 2021). It is the first disease-modifying therapy that has been approved for AD treatment and was followed by the approval of Lecanemab in the USA in 2023 (U.S Food and Drug Administration, 2023). Additionally, several mAbs (Donanemab, Gantenerumab, Solanezumab etc.) are currently in clinical trials (Cummings et al., 2024).

Another type of drug for AD that has been suggested is the use of metal chelators. Metal chelators are chemical compounds that bind to metal ions and modulate the metal balance in the body. In AD, the chelators may play a role by affecting pathological processes related to metals, especially those that involve copper, zinc and iron. The principle of chelators is that they bind specifically and create complexes which redistribute metal ions or excrete them. In AD the aim would be to reduce or redistribute the levels of metal ions such as iron, copper and zinc which are most associated with aggregation of A $\beta$ , oxidative stress, and also found in elevated levels in amyloid plaques. A few drugs have been suggested: Clioquinol and PBT2 bind specifically to Cu and Zn and have been shown to reduce number of A $\beta$  aggregates and improve cognitive function in animal models. Additionally, iron and zinc chelators have also been tested (deferrioxamine, deferasirox and TMEDA) to reduce the oxidative stress caused by the metal ions. However, none of the metal chelators mentioned above are available for the treatment of AD, as more studies are needed to ensure safety and minimize the side effects. Since the role of metals in AD is not yet fully understood, new insights are likely required before treatments with metal chelators can be used in AD (Budimir, 2011; Kenche & Barnham, 2011; Sharma et al., 2018). Additionally lipoic acid, which is a strong antioxidant that has been shown to have metal-chelating properties and have been suggested as a potential redistributor of copper in AD (Kirss et al., 2024).

## 2 Aims of the study

During the last decades, the connection between Alzheimer's disease and metals has been extensively studied. The aim of the current thesis has been to further examine the effect of metals on AD related proteins and peptides.

- I. To investigate the interaction of inorganic mercury with different isoforms of the Apolipoprotein E protein and examine how the secondary structure of the protein is affected.
- II. To investigate the interactions between Ni(II) ions and A $\beta$  peptides, focusing on the metal-binding properties, the effects on A $\beta$  structure and aggregation.
- III. To determine if different ATCUN motifs show different Cu(II)-binding affinities under the conditions of direct competition with HSA and elucidate whether truncated A $\beta$  peptides with ATCUN motifs can compete with HSA for the binding of Cu(II) ions.
- IV. To monitor the effects of uranyl ions on the structure and aggregation of different A $\beta$  species.

### 3 Materials and methods

Publication I: Mercury Ion Binding to Apolipoprotein E Variants ApoE2, ApoE3, and ApoE4: Similar Binding Affinities but Different Structure Induction Effects

- Fluorescence measurements: titration of Hg ions to monitor changes in intrinsic tryptophan fluorescence.
- Circular dichroism: titration of Hg ions to ApoE variants to determine the effect on secondary structure.

Publication II: Residue-specific binding of Ni(II) ions influences the structure and aggregation of amyloid beta (A $\beta$ ) peptides

- NMR spectroscopy: molecular details of Ni(II) binding to A $\beta$  monomer and estimation of Ni binding affinity to A $\beta$ .
- Circular dichroism: monitoring change in secondary structure of A $\beta$  upon addition of Ni(II) ions.
- ThT fluorescence assay: effect of Ni(II) ions on kinetics of A $\beta$ 40 aggregation
- AFM imaging: characterization of morphology of A $\beta$ 40 aggregates.
- BN-PAGE analysis.
- FTIR spectroscopy of A $\beta$  oligomers.
- Fluorescence microscopy: monitoring formation of dityrosine crosslinks.

Publication III: Direct Competition of ATCUN Peptides with Human Serum Albumin for Copper(II) Ions Determined by LC-ICP MS

- Competition of ATCUN Peptides with Human Serum Albumin for Cu(II) ions.
- LCP-ICP MS analysis.
- Data analysis for determination of relative dissociation constants.

Publication IV: Characterization of Uranyl (UO $_2^{2+}$ ) Ion Binding to Amyloid Beta (A $\beta$ ) Peptides: Effects on A $\beta$  Structure and Aggregation

- Monitoring of A $\beta$  aggregation by ThT fluorescence.
- TEM imaging of aggregated A $\beta$ 40 peptides.
- NMR spectroscopy: binding of uranyl to A $\beta$ 40 monomers.
- Fluorescence measurements to determine binding affinity of uranyl to A $\beta$  via quenching of Tyr10 fluorescence.
- Circular dichroism: monitoring changes in the secondary structure of A $\beta$  upon addition of UO $_2^{2+}$  ions.
- BN-PAGE analysis.
- FTIR spectroscopy.

## 4 Results

**Publication I:** Mercury Ion Binding to Apolipoprotein E Variants ApoE2, ApoE3, and ApoE4: Similar Binding Affinities but Different Structure Induction Effects

- Hg(II) ions have similar binding affinity to all three Apolipoprotein E variants ApoE2, ApoE3 and ApoE4, indicating that the cysteine residues in position 112 and 158 are not involved in binding of metal ions.
- Titration to the ApoE peptide with Hg(II) ions affects their secondary structure differently, the largest change can be observed in ApoE4.

**Publication II:** Residue-specific binding of Ni (II) ions influences the structure and aggregation of amyloid beta (A $\beta$ ) peptides

- Specific binding of Ni(II) ions to the N-terminal region of the A $\beta$ <sub>40</sub> peptide was observed at neutral pH (7.3) but not at acidic pH (5.1). In the presence of a membrane-mimicking system (SDS micelles), no effect was observed on the C-terminal, while the N-terminal was largely affected.
- Addition of Ni (II) ions to A $\beta$  peptides in aqueous buffer reduces intensity while the shape of CD spectra remains unaffected. This suggests that Ni(II) ions induce precipitation and reduce A $\beta$  in solution.
- Ni(II) ions induce structural changes in A $\beta$ <sub>40</sub> WT and A $\beta$ <sub>4-40</sub> in aqueous buffer solution, indicating the transition of polyproline II helix structures into random coil structures.
- In membrane mimicking environment the peptide takes an alpha helical structure. Titration of Ni(II) ions reduce the intensity at 208nm but not at 222nm, indicating an increase in superhelicity.
- The estimated dissociation constant for the A $\beta$ <sub>40</sub>-Ni(II) complex is in the low  $\mu$ M range.
- At sub-stoichiometric Ni(II):A $\beta$ <sub>40</sub> ratios, the Ni(II) ions slow down the A $\beta$ <sub>40</sub> fibrillization kinetics in a concentration-dependent manner.
- Results of IR and PAGE studies indicate that the addition of Ni(II) ions appears to interfere with the SDS-induced conversion of A $\beta$ <sub>42</sub> monomers into homogenous and stable oligomeric structures, instead favoring the formation of larger and more heterogenous oligomer populations.
- Incubation of A $\beta$ <sub>40</sub> and Ni(II) ions induces formation of dityrosine crosslinks.

**Publication III:** Direct Competition of ATCUN Peptides with Human Serum Albumin for Copper(II) Ions Determined by LC-ICP MS

- ATCUN and truncated A $\beta$  peptides (A $\beta$ <sub>4-16</sub> and A $\beta$ <sub>11-15</sub>) bind Cu(II) ions with an affinity similar to that for human serum albumin.
- Other ATCUN-containing peptides also have similar Cu(II)-binding affinities.

**Publication IV:** Characterization of Uranyl  $\text{UO}_2^{2+}$  Ion Binding to Amyloid Beta (Abeta) Peptides: Effects on Abeta Structure and Aggregation

- $\text{UO}_2^{2+}$  ions inhibit the formation of  $\text{A}\beta$  amyloid fibrils in a concentration-dependent manner, with complete inhibition at stoichiometric uranyl/ $\text{A}\beta_{40}$  ratios.
- Uniformly distributed, concentration dependent intensity loss of amide-cross-peak intensity in NMR spectra occurs at both pH 7.3 and 5.1.
- $\text{UO}_2^{2+}$  ions bind with higher affinity to  $\text{A}\beta_{40}$  WT and  $\text{A}\beta_{40}$  NoHis at a lower pH.
- A structural transition in  $\text{A}\beta$  from random coil to  $\beta$ -sheets occurs upon titration of  $\text{UO}_2^{2+}$  ions at pH 5.1.
- $\text{UO}_2^{2+}$  ions are not able to induce dityrosine crosslinks under the experimental conditions used.

## 5 Discussion

Alzheimer's disease is characterized by progressive cognitive decline and memory impairment, with an inevitable fatal outcome. It is a challenging disorder that places a great emotional burden on the patients and their families as well as a significant economic burden on society. Despite extensive investigation over several decades, many details regarding the pathogenesis of AD are still unknown.

The A $\beta$  peptides are considered central to AD pathology and most likely play a critical role in the development and progression of the disease. Although the amyloid cascade hypothesis and the role of A $\beta$  in AD pathogenesis is under debate, it is generally accepted that peptide plays an important role in AD pathogenesis. However, there is still disagreement about whether A $\beta$  aggregation is the cause of the disease, or a consequence contributing to disease progression. It has been shown that the A $\beta$  peptide exerts toxicity to cells during the aggregation process while preformed mature fibrillar aggregates show little or no toxicity (Krishtal et al., 2017). Therefore, understanding the aggregation process and the behavior of the A $\beta$  peptide is crucial to understanding AD. Today, the oligomeric forms of A $\beta$  are considered the most toxic species. Although the toxic mechanism is still unclear, it is believed to involve membrane disruption and induction of Ca-leakage (Wärmländer et al., 2019). Studying oligomeric A $\beta$  species is therefore of great importance. However, as the oligomeric species are very unstable, their studies are complicated. To stabilize the oligomers detergents or fatty acids are often used (Vosough & Barth, 2021). Because there are many ways to prepare A $\beta$  oligomers, there is also considerable variation in their reported properties, which makes it difficult to compare results and reach a consensus. It should be mentioned that A $\beta$  peptides are in general extremely sensitive to variations in the experimental conditions. Factors such as pH, temperature, concentration, agitation, and access to surfaces or other interfaces may have large effects on the peptide's behavior. It is imperative to consider this when performing experiments and comparing results.

Metal ions such as copper, zinc and iron have for a long time been implicated in AD pathology, although their exact role remains unclear. They have been shown to interact with the A $\beta$  peptide, influence aggregation, and possibly also promote the formation of toxic oligomeric species. Redox-active metal ions are furthermore known to induce ROS, which may cause further cellular and molecular damage. It is not yet clear if metal dyshomeostasis is a cause or an effect of the disease. It is also not clear if the formation of large aggregates is formed as a result of metal ions influencing the A $\beta$ -peptide, or if the already formed aggregates attract metal ions. Either way, the metal ions seem to be involved in the pathological processes of AD, and possibly exacerbate it.

Metal binding to the A $\beta$  peptide has been the focus in three of the papers in this thesis. Variants of the full length A $\beta$ -peptide were the main focus in paper II and IV. Paper III instead focused on shorter, truncated segments of the peptide (A $\beta$ <sub>4-16</sub> and A $\beta$ <sub>11-15</sub>), which have a histidine residue at the third position, thereby forming ATCUN-motifs (NH<sub>2</sub>-X-Z-H). ATCUN-motifs are known to bind certain metal ions with high affinity through square planar geometry coordination involving-terminal amino group, two adjacent peptide nitrogens, and nitrogen from the histidine residue at position three.

The truncated, ATCUN motif-containing A $\beta$ <sub>4-42</sub> and A $\beta$ <sub>11-42</sub> peptide fragments have been found in high concentrations in plaques of AD brains (Liu et al., 2006; Naslund et al., 1994; Portelius et al., 2010). The ATCUN configurations likely allow high-affinity metal binding to these peptide fragments, thereby probably altering the metal-peptide

interactions compared to the full-length peptide. Removal of the first three amino acids (Asp1, Ala2, Glu3) of the A $\beta$  peptide furthermore reduces the overall negative charge of the peptide. It has been suggested that truncation of the N-terminal might increase the aggregation rate of the peptide, although the overall toxicity seems to be similar for A $\beta_{4-x}$  peptides and full-length peptides (Bouter et al., 2013; Pike et al., 1995; Wirths et al., 2019). The truncation also affects the conformation of the peptide. A $\beta_{4-x}$  peptides may have a stronger propensity to form  $\beta$ -sheets, due to the increased hydrophobicity (Karkisaval et al., 2020; Pike et al., 1995). In this thesis, structural studies have been performed on the A $\beta_{4-40}$  peptide with CD spectroscopy. No significant structural differences between the truncated- and full-length peptides were observed with this method (Figure 3, paper II). It should be pointed out that CD measurements are not very exact, as they report on the average secondary structure content in the sample. The truncated A $\beta_{4-16}$  peptide has been reported to bind Cu(II) ions with similar affinity than human serum albumin (HSA), where the latter normally binds a substantial amount of the body's circulating copper in the body (Kirsipuu et al., 2020). Interestingly, we showed that short peptides with ATCUN motifs could not remove substantial amounts of Cu(II) ions from excess HSA in blood and CSF environments (Paper III). We also investigated the interactions between full-length A $\beta$  peptides, nickel(II) and uranyl ions, respectively. Interestingly, both Ni(II) and UO $_2^{2+}$  ions induce structural changes and inhibit the fibrillation pathway of the peptide, although through different mechanisms. The uranyl ions did not show residue-specific binding to A $\beta$ . Instead, the observed interaction effects are likely caused by electrostatic interactions between the cationic uranyl ion and the anionic peptide. For the Ni(II) ion, on the other hand, we observed specific binding to N-terminal residues, especially histidines. This result shows that metal ions can affect the peptides via various modes of interaction. For example, when the peptide is in membrane-mimicking environments, the A $\beta$  peptide typically adopts  $\alpha$ -helical conformations. CD spectroscopy can then be used to measure the characteristic CD intensities at 208 nm and 222 nm, where the  $\theta_{222}/\theta_{208}$  ratio reflects the amount of superhelicity in the sample (Barbar & Nyarko, 2014). A clear increase in superhelicity, i.e.  $\alpha$ -helices wound around each other as coiled-coils, can be observed in the A $\beta_{1-40}$  WT and A $\beta_{4-40}$  samples when Ni(II) ions are added. The coiled-coil conformation might enhance peptide stability and could therefore influence the aggregation process (Lupas & Bassler, 2017). The uranyl ion did not show a similar induction of superhelicity, although a structural transition from random coil into  $\beta$ -sheet structure was observed for A $\beta$  peptides in aqueous solution. This structural change is thought to promote the A $\beta$  aggregation, although the Thioflavin T fluorescence curves and images from transmission electron microscopy show that uranyl ions inhibit the fibrillization of the peptide by directing it towards non-fibrillar, amorphous aggregates in a concentration-dependent manner.

The Ni(II) ions were found to induce dityrosine cross-links, which is a common effect of ROS action. Thus, Ni(II) ions may affect the A $\beta$  aggregation processes not only through direct interactions with the peptide, but also through ROS formation. Dityrosine-linked A $\beta$  dimers have been found in amyloid plaques in AD brains, most likely formed from ROS interactions, where the oxygen radicals might be created by the redox-active metal ions bound to the plaques (Berntsson et al., 2023; D. P. Smith et al., 2007; Williams et al., 2016). Since Ni(II) ions bind to the A $\beta$  N-terminal segment, mainly via histidine residues, it is possible that these metal ions can induce aggregation by coordinating histidine residues from several peptides. This would also position the Y10 residues in close

proximity, potentially facilitating the formation of dityrosine motifs. A $\beta$ -dimers linked together via covalent dityrosine bonds are more stable and resistant to dissociation compared to other non-covalently linked A $\beta$  dimers (Kok et al., 2013).

Although the A $\beta$  peptide is in the primary focus of AD research, the A $\beta$  peptide will probably not give us all the answers about the disease. Other proteins and biomolecules also play important roles in AD. For example, the lipoprotein ApoE has been found within the amyloid plaques of AD patients, and the ApoE4 isoform is today the main genetic risk factor for developing sAD (Corder et al., 1993; Liao et al., 2004; Mishra et al., 2018). Interestingly, ApoE has been suggested to be involved in the clearance of metal ions and/or A $\beta$  peptides from the brain. This conclusion is supported by the facts that the carriers (homo-/heterozygotes) of the ApoE4 isoform are more susceptible to mercury toxicity and have a higher risk of developing AD. In paper I of this thesis, we studied the effect of mercury ions on ApoE by monitoring changes in the secondary structure of the protein, as well as determining the apparent binding affinity for Hg(II) ions. Earlier, it has been suggested that the ApoE4 isoform may be less effective in metal binding as this isoform lacks cysteine residues at positions 112 and 158. Interestingly, the binding affinities for Hg(II) ions turned out to be virtually the same for all three isoforms, showing that Cys112 and Cys158 are not involved in Hg(II)-binding. Yet, binding of Hg(II) ions affected the secondary structure of the ApoE variants differently - the superhelicity increased more in ApoE4 than in ApoE2 and ApoE3. A previous study has shown that the C-terminal ApoE segment has a propensity to form superhelices, stabilized by salt bridges, and our results may therefore be explained by structural changes in this segment (Choy et al., 2003). It should be mentioned that the three ApoE isoforms have different initial secondary structures, as the variations at position 112 and 158 affect the protein structure. For example, it has been suggested that interactions between Arg61 and Glu255 would pull the N- and C-terminal segments closer to each other. This interaction does not happen when Cys112 is present, due to interactions between Cys112 and Arg61. With this initial difference, it is reasonable that addition of Hg(II) ions induces different structural alterations in the different isoforms. It has furthermore been shown that when ApoE is in a lipid-free solution, then the C-terminal segment promotes tetramerization, as the hydrophobic residues are positioned in the center of the tetramer and become protected from the aqueous environment. Such structural effects could potentially also affect the metal-binding properties of the protein (Horn et al., 2023).

This thesis adds new knowledge about the interactions AD-related proteins and peptides with metal ions, which provides new insights into the disease mechanism, and thereby helps to solve the large puzzle of Alzheimer's disease.

## Conclusions

- I. All three isoforms of Apolipoprotein E (ApoE2, ApoE3 and ApoE4) were found to bind mercury ions with similar binding affinities. Yet, the Hg(II) ions induce different structural changes in the isoforms, with the largest changes in ApoE4. The changes observed are interpreted as increased superhelicity, due to the effects on the  $\theta_{222}/\theta_{208}$  ratio in CD spectra. The results show that Hg binding is likely coordinated by other amino acids than Cys112 and Cys158, which are present in ApoE2 (Cys112 and Cys158) and ApoE3 (Cys112). Weaker Hg (II) binding was seen at pH 5, indicating that histidines are involved (i.e., His140 and His 299), although multiple binding sites are likely present. The binding affinity of Hg(I) ions is much weaker than that of divalent Hg(II) ions which suggests that the potentially harmful interactions between ApoE and Hg are happening in the oxidizing extracellular environment.
- II. Ni(II) ions bind to the N-terminal segment of A $\beta$ , with a binding affinity in the low  $\mu$ M range. The binding of Ni(II) ions affects the fibrillization process, and at equimolar amounts directs the aggregation away from fibrillar structures and towards amorphous aggregates. The bound Ni ions induce the formation of dityrosine cross-links via redox chemistry, thereby creating covalent A $\beta$  dimers. Secondary structure alterations are observed upon the addition of Ni(II) ions, both in an aqueous environment and in a membrane-mimicking environment. Stoichiometric amounts of Ni(II) ions promote the formation of heterogeneous A $\beta$  oligomers. Since the oligomers are considered the most toxic species of A $\beta$  aggregates, this might contribute to AD brain pathology.
- III. Cu ions bind to truncated ATCUN-containing A $\beta$  peptides with similar affinity as to human serum albumin. The ATCUN motif-containing peptides do not remove substantial amounts of Cu(II) ions from excess human serum albumin in blood and CSF environments.
- IV. Uranyl ions bind to the A $\beta$  peptide via non-specific electrostatic interactions, with the strongest binding affinity observed at pH 5.1. Weaker binding was observed at physiological pH values, potentially explained by interference from His sidechains or by the presence of other uranyl species. The uranyl ions inhibit A $\beta$  fibrillization already at sub-stoichiometric concentrations and induce structural changes in both monomeric and oligomeric A $\beta$  species.

## Acknowledgements

First, I would like to express my sincere gratitude to my supervisor **Peep Palumaa** for all the guidance, help and patience. I am grateful that you believed in and supported me on this journey.

Thank you to my co-supervisor **Sebastian Wärmländer**, for always being available for discussion and helping me on every step of the way. Your constant encouragement and for pushing me has been invaluable. I could not have done this without your help and guidance.

To my other co-supervisor **Per Roos**, thank you for all the good discussions, feedback and great ideas.

I would also like to thank **Astrid Gräslund** for letting me into her lab with open arms. Thank you for all the great discussions and your enthusiasm. It has been an honor to be a part of your research.

To **Jüri Jarvet**, thank you for everything. Thank you for always being there to help, to discuss results and thank you for your honest opinions.

In the **Palumaa Lab**, special thank you to **Merlin Friedmann**, **Andra Normägi** and **Julia Smirnova** for welcoming me with open arms, letting me be a part of your projects and teaching me your methods. Also, thanks to **Vello Tõugu** for all great input on data and analysis.

During my years in the **Gräslund Lab**, I have had the opportunity to work with many amazing people. Thank you, **Amanda Lakela**, **Fanny Asplund**, **Nicklas Österlund**, **Xiaolin Dong** and many others for all collaborations.

In the **Andreas Barth group**, Thank you **Andreas**, **Faraz Vosough** and **Suman Paul** for many fruitful collaborations. I would also like to thank the **Ludmilla A Morozova-Roche** lab at Umeå University, for the great collaborations.

This thesis work has been supported by Estonian Research Council (grant PRG 1289). This work has also been partially supported by TUT Institutional Development Program for 2016–2022 Graduate School in Biomedicine and Biotechnology receiving funding from the European Regional Development Fund under program ASTRA 2014–2020.4.01.16-0032 in Estonia.

And to my family,

**Mum**, Mammut. Thank you for all the endless love and support. *Alltid oavsett*. To **Kennie** and **Linda**, thank you for all the insightful discussions and all the inspiration. **Louna**, you have brought me so much happiness, you are the best!

**Pappa**, thanks for never being more than a phone call away when I needed to disconnect and just think about something else.

**Peter**, my dear uncle. Thank you for always keeping me on my toes, asking questions and being interested.

To **Bengt** and **Lise**, thank you for your kindness, encouragement and support during this time. To the rest of the **Mattsson** and **Langseth** family, thank you for your warmth and generosity along the way.

To **Vilma**. Thank you for changing everything, for giving me new a perspective and purpose.

Finally, thank you **Christoffer**. Thank you for the all the peptalks when I was ready to give up, and for picking up the pieces when I already had. Thank you for always being there, for being my safe place and for supporting and encouraging me on every step of the way.

## Abstract

### Interaction of metal ions with peptides and proteins related to Alzheimer's disease

Alzheimer's disease (AD) is the most common cause of dementia with approximately 55 million patients worldwide. The disease has been studied for decades, and although significant progress has been made, there are still many gaps in our knowledge. So far, no effective disease-modifying treatments have been developed, despite ongoing efforts. The underlying molecular mechanisms remain debated, but it is widely accepted that aggregation of the amyloid- $\beta$  (A $\beta$ ) peptide is involved in the disease pathology.

The A $\beta$  peptide is known to self-assemble into aggregates, ranging from dimers to lots of peptides, with large amyloid plaques as the end-product. Many hypotheses have been proposed regarding the cause of the disease. One of them is the metal hypothesis, which argues that metal dysregulation plays a crucial role in AD pathology. Increased levels of Cu, Fe and Zn have been found in the amyloid plaques of AD brains; however, the mechanism of metal involvement remains to be elucidated. There are indications that some metals can affect the cleavage of the A $\beta$  precursor protein, thereby increasing the A $\beta$  production, particularly the more aggregation-prone A $\beta$  variants. Additionally, it has been suggested that metal ions affect the aggregation pathway of the A $\beta$  peptide, and to some extent stabilize toxic oligomeric species. A third possibility is that the metals are not actually involved in the aggregation. Instead, they might bind to already formed aggregates and contribute to the formation of harmful oxygen radicals.

In this thesis, some effects of metal ions on AD-related proteins have been investigated. Significant work has previously been published on the most biologically relevant metals, such as Cu, Zn and Fe, although with a lot of variations in the results. We were able to show that the truncated A $\beta$  peptides containing an ATCUN-motif have similar binding affinities to Cu(II) as the well-known Cu(II) binding protein human serum albumin (HSA). It can be concluded that the truncated A $\beta$  variants with an ATCUN-motif are not able to remove substantial amounts of Cu(II) ions from HSA in blood or CFS and do likely not have a dominant role in the regulation of Cu(II) ions in these environments.

We also wanted to contribute to the field by investigating metals that are available in our environment, but which are not required for any biological processes in the human body. These studies can provide insights into the general mechanism of metal-induced peptide aggregation and toxicity. The selected metals are nickel, mercury, and uranium.

We show that both nickel and uranium can slow down the fibrillization kinetics and direct the aggregates towards amorphous structures. The Ni(II) ions bind specifically to the N-terminal, particularly to the His residues and were also shown to induce the formation of dityrosine crosslinks, which generates aggregates that are more stable and more resistant to dissociation. The uranyl ions on the other hand did not show specific binding and are instead thought to interact with the peptide through electrostatic interactions. Interestingly, the uranyl ions showed strongest binding at pH 5.1, which could be explained by interference of the His sidechains at neutral pH and by the chemical properties of the uranyl ions that might become hydrolyzed at low pH. Therefore, the presence of monomeric and dimeric hydroxyl species mixed with the uranyl ions might affect the binding. Both Ni(II) and uranyl ions were able to induce  $\beta$ -sheet formation in aqueous solution and thereby stabilizing and promoting aggregation of the peptide.

Although the A $\beta$  peptide is of great interest, there are many other peptides and proteins that are involved in AD. The apolipoprotein ApoE occurs in three isoforms, where the ApoE4 has been shown to be the main genetic risk factor for developing sporadic AD. Interestingly, ApoE4 carriers have also been shown to be more susceptible to mercury toxicity. Therefore, it has been suggested that the ApoE protein might be involved in the clearance of Hg and/or A $\beta$  peptides, and that the ApoE4 isoform might be less effective at this task.

We showed that the binding affinity for Hg(II) ions is largely the same for all three ApoE isoforms, but that a larger structural change can be observed for the ApoE4 isoform upon addition of Hg(II) ions. This indicates that the amino acid variations between the different isoforms are not directly involved in the binding of Hg(II) ions, but that the differences in structure induction might be connected to the ApoE- $\epsilon$ 4 gene being a risk factor for mercury intoxication.

In this thesis, the studied peptides/proteins are different variants of amyloid- $\beta$ , ApoE, and human serum albumin. Numerous biophysical methods, mainly spectroscopic and imaging techniques, have been used to characterize different aspects of the interactions between the selected metal ions and the protein/peptide variants. The focus has been to determine binding affinities, identify specific binding residues, and to monitor metal-induced effects on secondary structure and aggregation of selected peptides/proteins. The obtained results widen our insights into the role of metal ions in AD pathology, highlighting specific interactions that may influence the progression of the disease.

## Lühikokkuvõte

### Metallioonide interaktsioonid Alzheimeri tõvega seotud peptiidide ja valkudega

Alzheimeri tõbi (AD) on kõige levinum dementsuse põhjus, mõjutades umbes 55 miljonit inimest üle kogu maailma. Haigust on uuritud kümneid aastaid ja kuigi on tehtud märkimisväärseid edusamme, on meie teadmistes endiselt palju lünki. Vaatamata jätkuvatele pingutustele pole seni veel välja arendatud tõhusaid haigust muutvaid ravimeetodeid. Haiguse aluseks olevad molekulaarsed mehhanismid on endiselt vaieldavad, kuid on laialdaselt aktsepteeritud, et amüloidi- $\beta$  ( $A\beta$ ) peptiidi agregatsioon on seotud haiguse patoloogiaga.

$A\beta$  peptiid on tuntud oma võime poolest ise kokku koonduda agregaatideks, mis hõlmavad nii oligomeere, kui ka paljudest peptiididest koosnevaid amüloidseid naastusid. On pakutud välja mitmeid hüpoteese, mis käsitlevad haiguse põhjust. Üks neist on metallide hüpotees, mis väidab, et metallide düsregulatsioon mängib AD patoloogias olulist rolli. Näiteks Cu, Fe ja Zn, kõrge kontsentratsioon on leitud AD ajus amüloidsetes naastudes, kuid metallide osaluse mehhanism on veel uurimisjärgus. On viiteid sellele, et mõned metallid võivad mõjutada  $A\beta$  eellasvalgu lõhustumist, suurendades rohkem agregatsioonile kalduvate  $A\beta$  peptiidide tootmist. Lisaks võivad metallioonid mõjutada  $A\beta$  peptiidi agregatsiooniteed ja osaliselt stabiliseerida toksilisi oligomeerseid vorme. Kolmanda võimaluse kohaselt ei osale metallid  $A\beta$  agregatsioonis, kuid selle asemel võivad nad seostuda juba moodustunud agregaatidega ja aidata kaasa kahjulike hapniku radikaalide tekkele.

Käesolevas töös on uuritud mõningate metallioonide mõju AD-ga seotud valkudele. Varasemalt on teostatud mahukas töö bioloogiliselt kõige olulisemate metallide kohta, nagu Cu, Zn ja Fe, kuigi tulemused varieeruvad. Me suutsime näidata, et lühenenud  $A\beta$  peptiid, mis sisaldab ATCUN-motiivi, seondub Cu(II)-ioonidega sarnaselt tuntud Cu(II) siduva valgu - inimese seerumi albumiiniga (HSA). Võib järeldada, et lühenenud  $A\beta$  variandid, mis sisaldavad ATCUN-motiivi, ei suuda veres või tserebrospinaalvedelikus eemaldada Cu(II) ioone HSA-lt ja ei mängi tõenäoliselt domineerivat rolli Cu(II) ionide regulatsioonis neis keskkondades.

Soovisime samuti panustada valdkonda, uurides metalle, mis esinevad meie keskkonnas, kuid mis ei ole inimorganismi funktsioneerimiseks vajalikud. Need uuringud võivad anda täiendavat informatsiooni metallioonide poolt põhjustatud peptiidide agregatsiooni ja toksilisuse üldmehhanismide kohta. Valitud metallideks olid nikkel, elavhõbe ja uraan.

Me näitasime, et nii nikkel(II), kui ka uraanüülioonid suudavad aeglustada  $A\beta$  fibrilliseerumise kineetikat ja suunata protsessi amorfsete agregaatide tekke suunas. Ni(II) ioonid seonduvad spetsiifiliselt  $A\beta$  N-terminaalses osas paiknevate His-jääkidega, ning suudavad samuti indutseerida ditürosiini-ristsidemete moodustumist, mis tekitab stabiilsemad ja dissotsiatsioonile vastupidavamad agregate. Uraanüülioonid seevastu ei näidanud spetsiifilist sidumist  $A\beta$ -ga, millest järeldub, et need ioonid mõjutavad peptiidide elektrostaatiliste interaktsioonide kaudu. Uraanüülioonid näitasid tugevamat sidumist pH-l 5,1 juures, mida võiks selgitada His-külgahelate segava toimega neutraalses pH alas ja uraanüülioonide keemiliste omadustega, mis võivad madalal pH-l hüdrolüüsuda. Seetõttu võib monomeersete ja dimeersete hüdroksüülühendite ja uraanüülioonide segu mõjutada seostumist. Nii Ni(II) kui ka uraanüülioonid suutsid

indutseerida  $\beta$ -lehtstruktuuride moodustumist vesilahuses ja seeläbi stabiliseerida ja soodustada A $\beta$  peptiidi agregatsiooni.

Kuigi A $\beta$  peptiid on oluline huviobjekt, on palju teisi peptiide ja valke, mis on seotud AD-ga. Apolipoproteiin ApoE esineb kolmes isovormis, kus ApoE4 on peamine geneetiline riskitegur sporaadilise AD tekkes. On huvitav märkida, et ApoE4 kandjate puhul on näidatud, et nad on ka tundlikumad elavhõbeda toksilisusele. Seetõttu on välja pakutud, et ApoE valk võib osaleda elavhõbeda ja/või A $\beta$  peptiidide väljutamises organismist ning et ApoE4 isoform võib olla vähem efektiivne selle ülesande täitmisel. Näitasime, et elavhõbe (Hg(II)) ionide sidumisafiinsus on kõigi kolme ApoE isoformi puhul küllalt sarnane, kuid Hg(II) ionide lisamisel on ApoE4 isoformi puhul täheldatav suurem struktuuri muutus. See viitab sellele, et erinevate isoformide vahelised järjestuse variatsioonid ei osale otseselt Hg(II) ionide sidumises, kuid struktuuri indutseerimise erinevused võivad olla seotud ApoE4 suurema elavhõbedamürgituse riskiteguriga.

Käesolevas töös uuritud peptiidid/valgud on erinevad A $\beta$  variandid, ApoE ja HSA. Erinevate metallioonide ja valgu/peptiidi variantide vaheliste interaktsioonide iseloomustamiseks on kasutatud mitmesuguseid biofüüsikalisi meetodeid. Fookus on olnud sidumisafiinsuste määramisel, spetsiifiliste sidumiskohtade tuvastamisel ning metallide poolt põhjustatud mõjude jälgimisel valkude/peptiidide sekundaarstruktuurile ja agregatsioonile. Saadud tulemused laiendavad meie arusaama metallioonide rollist AD patogeneesis, tuues esile spetsiifilised interaktsioonid, mis võivad mõjutada haiguse progresseerumist.

**ABSTRACT:** Mercury intoxication typically produces more severe outcomes in people with the *APOE-ε4* gene, which codes for the ApoE4 variant of apolipoprotein E, compared to individuals with the *APOE-ε2* and *APOE-ε3* genes. Why the *APOE-ε4* allele is a risk factor in mercury exposure remains unknown. One proposed possibility is that the ApoE protein could be involved in clearing of heavy metals, where the ApoE4 protein might perform this task worse than the ApoE2 and ApoE3 variants. Here, we used fluorescence and circular dichroism spectroscopies to characterize the *in vitro* interactions of the three different ApoE variants with Hg(I) and Hg(II) ions. Hg(I) ions displayed weak binding to all ApoE variants and induced virtually no structural changes. Thus, Hg(I) ions appear to have no biologically relevant interactions with the ApoE protein. Hg(II) ions displayed stronger and very similar binding affinities for all three ApoE isoforms, with  $K_D$  values of 4.6  $\mu\text{M}$  for ApoE2, 4.9  $\mu\text{M}$  for ApoE3, and 4.3  $\mu\text{M}$  for ApoE4. Binding of Hg(II) ions also induced changes in ApoE superhelicity, that is, altered coil–coil interactions, which might modify the protein function. As these structural changes were most pronounced in the ApoE4 protein, they could be related to the *APOE-ε4* gene being a risk factor in mercury toxicity.

## 1. INTRODUCTION

Mercury (Hg) is a toxic metal that contributes to severe and permanent health problems and even death.<sup>1–4</sup> According to the Global Mercury Assessment 2018 report,<sup>5</sup> the estimated global anthropogenic emission of mercury to the atmosphere was approximately 20% higher in 2015 than in 2010. Most of these emissions originate from industrial activities related to mining and coal and oil combustion,<sup>5</sup> where Asia is responsible for 49% of the total emissions, followed by South America (18%) and Sub-Saharan Africa (16%). Hg is neurotoxic and genotoxic and induces damage to organs such as the brain and kidneys.<sup>1,2,6</sup> The different forms of Hg, that is, metallic, inorganic such as Hg(I), and Hg(II) ions, and organometallic complexes such as methyl-Hg and ethyl-Hg, have different properties and toxicity profiles.<sup>1,2</sup> Mercury vapor and organic Hg readily pass through membranes such as the blood–brain–barrier and the placental barrier, and thus become distributed throughout the entire human body including the fetus.<sup>7–9</sup> Developing neurites<sup>10</sup> and growing organs seem to be particularly susceptible to Hg damage, and Hg exposure is therefore especially harmful for children and fetuses.<sup>11–15</sup> The molecular mechanisms underlying Hg toxicity remain unclear,<sup>16</sup> but appear to include toxic molecular mimicry<sup>8</sup> and blocking of antioxidants<sup>17</sup> especially in the mitochondria.<sup>18</sup>

Interestingly, the susceptibility to Hg toxicity is influenced by genetic factors.<sup>19,20</sup> Notably, Hg exposure has been found to produce more severe outcomes in people with the *APOE-ε4* gene, which codes for the ApoE4 version of the apolipoprotein E protein, compared to individuals with the *APOE-ε2* and *APOE-ε3* genes.<sup>6,12–14,19,21–23</sup> *APOE-ε4* is also a genetic risk factor for Alzheimer's disease (AD),<sup>21,24–29</sup> and likely for other proteinopathies as well,<sup>30,31</sup> while Hg exposure might be an environmental risk factor for AD.<sup>28,32–35</sup> Why *APOE-ε4* carriers are more susceptible to both mercury intoxication and AD remains unclear. A number of possible explanations have been proposed,<sup>28,36,37</sup> including the possibility that the ApoE protein might be involved in the clearance of Hg and/or of amyloid- $\beta$  (A $\beta$ ) peptides,<sup>21,27,38</sup> whose aggregation plays a central role in AD pathology.<sup>39,40</sup>

**Figure 1.** Primary structure of the apolipoprotein E3 protein. The ApoE2 (Cys112 and Cys158), ApoE3 (Cys112 and Arg158), and ApoE4 (Arg112 and Arg158) variants differ in positions 112 and 158, marked in red. The regions known to adopt  $\alpha$ -helix conformations are shown in blue and green based on the information in Chen *et al.* 2011.<sup>49</sup>

Apolipoprotein E (ApoE) is a 299-residue-long (34 kDa) glycoprotein (Figure 1) involved in lipid metabolism: it transports lipid-soluble vitamins and lipids such as cholesterol in the central nervous system, into the lymph system, and then into the blood.<sup>41–43</sup> In the brain, ApoE is mainly produced by the astrocytes and microglial cells and interacts with ApoE receptors.<sup>38,44</sup> The three common variants of the ApoE protein differ at residues 112 and 158, that is, ApoE2 (Cys112 and Cys158), ApoE3 (Cys112 and Arg158), and ApoE4 (Arg112 and Arg158).<sup>22,42</sup> As the cysteine –SH groups are capable of binding metal ions including Hg ions,<sup>35,45–47</sup> it has been speculated that the ApoE residues Cys112 and Cys158 might bind Hg ions, which subsequently could be transported out from the tissue.<sup>6,21,22,28,46,48</sup> ApoE4 would then not be able to perform this task very well as it has Arg instead of Cys residues at positions 112 and 158 (Figure 1). Mercury would then accumulate in the tissues of APOE- $\epsilon$ 4 individuals, which would aggravate the toxic effects, which possibly could include Hg-induced neurodegeneration and AD.<sup>6</sup> To the best of our knowledge, no one has so far tested this hypothesis experimentally. Here, we use the biophysical techniques circular dichroism (CD) and fluorescence spectroscopy to study *in vitro* the binding interactions between inorganic Hg(I) and Hg(II) ions and the three different ApoE protein variants.

## 2. MATERIALS AND METHODS

**2.1. Reagents and Sample Preparation.** Lyophilized ApoE2, ApoE3, and ApoE4 protein variants were purchased from AlexoTech AB (Umeå, Sweden) and stored at  $-20$  °C. All proteins were produced recombinantly with an additional methionine residue in position-1. The integrity of the proteins was confirmed by MALDI-TOF mass spectrometry. Before measurements, samples were dissolved in 10 mM NaOH (prepared in Milli-Q water) according to the manufacturer's instructions and then allowed to equilibrate at 4 °C for at least 1 h. The concentration was initially determined by weight and then confirmed by UV–vis spectroscopy. The samples were then diluted in either sodium phosphate buffer or MES [2-(N-morpholino)ethane sulfonic acid] buffer to a final buffer concentration of 20 mM at pH 7.3 or pH 5.5.

**2.2. Fluorescence Spectroscopy.** The binding affinities between Hg ions and ApoE variants were evaluated by fluorescence measurements using a LS-55 fluorescence spectrophotometer (PerkinElmer Inc., Waltham, MA, USA) equipped with a magnetic stirrer. In order to study both Hg(I) and Hg(II) ions, some measurements were carried out in the presence of 1 mM of the reducing agent TCEP [tris(2-carboxyethyl)phosphine], which reduces the Hg(II) ions from the HgCl<sub>2</sub> salt to the Hg(I) form. Small aliquots of HgCl<sub>2</sub>

(stock concentrations of 1, 2, or 10 mM) were titrated to a sample containing either 0.2 or 1.0  $\mu$ M ApoE protein in 20 mM MES buffer, pH 7.3 or 5.5, at 25 °C, in quartz cuvettes with a 5 mm path length. After each addition of HgCl<sub>2</sub>, the solution was stirred for 30 s before recording fluorescence emission spectra at 350 nm (excitation 276 nm). All titrations were repeated 3 times. The measured tryptophan fluorescence intensities were plotted against the concentration of Hg ions, and dissociation constants ( $K_D$ ) were evaluated by fitting the data curves to either eq 1 (the isotherm or hyperbolic equation together with a Hill coefficient)<sup>50</sup> or eq 2 (the Morrison equation)<sup>51</sup>

$$I = I_0 + \frac{(I_\infty - I_0) \cdot [\text{Hg}]^n}{K_D^n + [\text{Hg}]^n} \quad (1)$$

$$I = I_0 + \frac{I_\infty - I_0}{2 \cdot [\text{BS}]} \cdot \left( (K_D + [\text{Hg}] + [\text{BS}]) - \sqrt{(K_D + [\text{Hg}] + [\text{BS}])^2 - 4 \cdot [\text{Hg}] \cdot [\text{BS}]} \right) \quad (2)$$

Here,  $I_0$  is the initial fluorescence intensity with no added Hg ions,  $I_\infty$  is the steady-state intensity at the end of the titration,  $[\text{Hg}]$  is the concentration of the added Hg ions,  $K_D$  is the dissociation constant,  $n$  (in eq 1) is the Hill coefficient, and  $[\text{BS}]$  (in eq 2) is the concentration of the binding sites, which is equal to the protein concentration if the protein has a single binding site. Adding a term for the fluorescence quenching effect of free Hg ions appeared unnecessary.<sup>52</sup>

**2.3. CD Spectroscopy.** CD spectra were recorded between 190 and 260 nm with a step size of 0.5 nm and 5 s per data point at 20 °C using a Chirascan CD spectrometer from Applied Photophysics, UK. Samples of 5  $\mu$ M ApoE protein in 20 mM sodium phosphate buffer, pH 7.3, were measured in a quartz cuvette with an optical path length of 2 mm. Sodium phosphate buffer was used to avoid the interference of MES buffer with the CD measurements. In order to study both Hg(I) and Hg(II) ions, some measurements were carried out in the presence of 1 mM of the reducing agent TCEP, which reduces the Hg(II) ions from the HgCl<sub>2</sub> salt to the Hg(I) form. After the initial measurement of ApoE alone, 1–2  $\mu$ L HgCl<sub>2</sub> was added in steps from stock concentrations of 1, 2, or 10 mM to produce final HgCl<sub>2</sub> concentrations of 2, 5, 40, and 80  $\mu$ M. All titrations were repeated two or three times.

## 3. RESULTS AND DISCUSSION

**3.1. Fluorescence Spectroscopy.** To determine the binding strength of Hg(I) and Hg(II) ions to the ApoE isoforms, the quenching effect of the ions on the intrinsic tryptophan fluorescence was monitored. ApoE contains seven

**Figure 2.** Intrinsic ApoE tryptophan fluorescence upon titration with  $\text{HgCl}_2$  recorded at 350 nm (excitation 276 nm) for 0.2  $\mu\text{M}$  ApoE protein at +25  $^\circ\text{C}$  in 20 mM MES buffer either at pH 7.3 or pH 5.5. Black—ApoE2; red—ApoE3; blue—ApoE4; circles—pH 7.3; and squares—pH 5.5. Fitting eq 1 to the titration data produces apparent dissociation constants ( $K_D^{\text{app}}$ ).

tryptophan residues (Figure 1), which exhibit a strong fluorescence signal at 350 nm when excited around 276 nm.

Titration of  $\text{HgCl}_2$  to 0.2  $\mu\text{M}$  protein samples at either pH 7.3 or pH 5.5 produced the binding curves shown in Figure 2. Fitting eq 1 to the pH 7.3 curves yielded the dissociation constants ( $K_D$ ) for  $\text{Hg(II)}$  binding shown in Table 1, that is,

**Table 1.** Apparent  $K_D$  Values ( $K_D^{\text{app}}$ ) in  $\mu\text{M}$  for the ApoE· $\text{Hg(II)}$  Complex Obtained by Fitting Eq 1 to the pH 7.3 Fluorescence Titration Curves Shown in Figure 2

	titration 1	titration 2	titration 3	average $K_D$
ApoE2	$4.54 \pm 0.29$	$4.33 \pm 0.36$	$5.00 \pm 0.44$	4.62
ApoE3	$4.65 \pm 0.32$	$5.11 \pm 0.27$	$4.90 \pm 0.22$	4.89
ApoE4	$4.33 \pm 0.35$	$4.33 \pm 0.42$	$4.29 \pm 0.23$	4.32

on average 4.62  $\mu\text{M}$  for ApoE2, 4.89  $\mu\text{M}$  for ApoE3, and 4.32  $\mu\text{M}$  for ApoE4. The Hill coefficients ( $n$  in eq 1) were all found to be around 1, indicating little or no binding cooperativity. The hyperbolic equation (i.e., eq 1) was used as the protein concentration clearly was lower than the binding affinity of the studied complex. Even though MES is a good buffer devised to have minimal interactions with metal ions and other cations,<sup>53</sup> no corrections were made for potential interactions between the buffer and the  $\text{Hg(II)}$  ions. Thus, the calculated  $K_D$  values in Table 1 should be considered as apparent, that is,  $K_D^{\text{app}}$ . The most important thing about these  $K_D^{\text{app}}$  values is that they (and the corresponding binding curves) are all very similar. We therefore conclude that the  $\text{Hg(II)}$  ions are bound by the same (or at least very similar) binding sites in all three ApoE variants and that these binding sites do not involve as binding ligands the residues 112 and 158, which vary between the protein isoforms (Figure 1).

These conclusions clearly contradict the previously suggested hypothesis that different binding affinities to

mercury ions could explain why the *APOE-ε4* gene is a risk factor in Hg intoxication but not the *APOE-ε2* and *APOE-ε3* genes.<sup>6,21,22,28,46,48</sup> However, it cannot be ruled out that other forms of mercury, such as organic methyl-Hg or ethyl-Hg, could display different binding properties to the different ApoE variants. Future studies might investigate the details of ApoE binding to other forms of Hg than the inorganic ions studied here.

The  $\text{HgCl}_2$  titrations at pH 5.5 produced a much lower reduction in Trp fluorescence intensity than the titrations at pH 7.3 (Figure 2). This strongly indicates weaker binding of  $\text{Hg(II)}$  ions at acidic pH, even though no  $K_D$  values could be derived from these curves. The main difference in the proteins between pH 7.3 and pH 5.5 is protonation of His residues, which have  $\text{p}K_a$  values around 6.5.<sup>54</sup> As His residues are previously known to bind a range of metal ions, including  $\text{Hg(II)}$  ions,<sup>32</sup> and as protonation of His residues lowers their affinity for positively charged molecules, the different titration results at pH 7.3 and pH 5.5 shown in Figure 2 strongly suggest that His residues are involved in coordinating the  $\text{Hg(II)}$  ions. As shown in Figure 1, the ApoE proteins have two His residues, that is, His140 and His299.

Titrations with  $\text{HgCl}_2$  at pH 7.3 were also carried out at a slightly higher protein concentration, that is, 1.0  $\mu\text{M}$  (Figure 3). As the protein concentration is now close to the binding affinity, it is not appropriate to fit the binding curves with the hyperbolic/isotherm eq 1. The data was instead fitted with eq 2, where the binding site concentration is included as one of the fitted parameters. For the  $\text{Hg(II)}$  ion titrations, eq 2 produced average  $K_D$  values around 4.2 (ApoE2), 4.1 (ApoE3), and 4.8 (ApoE4). These  $K_D$  values are very close to those obtained at 0.2  $\mu\text{M}$  ApoE concentration (Figure 2 and Table 1), thus confirming their accuracy. The fittings to eq 2 also produced binding site concentrations around 10  $\mu\text{M}$ , for all three proteins. Although this should be regarded as an

**Figure 3.** Intrinsic ApoE tryptophan fluorescence upon titration with  $\text{HgCl}_2$  recorded at 350 nm (excitation 276 nm) for 1  $\mu\text{M}$  ApoE protein in 20 mM MES buffer, pH 7.3 at +25  $^\circ\text{C}$ . Black—ApoE2; red—ApoE3; blue—ApoE4; circles— $\text{Hg(II)}$  ions; and triangles— $\text{Hg(I)}$  ions (1 mM TCEP added). Fitting eq 2 to the titration data produces apparent dissociation constants ( $K_D^{\text{app}}$ ).

approximate number, it is clearly larger than the protein concentration of 1  $\mu\text{M}$ . This indicates that there are multiple binding sites for  $\text{Hg(II)}$  ions on all three ApoE variants.

Adding 1 mM of the reducing agent TCEP reduces the  $\text{Hg}$  ions to their monovalent  $\text{Hg(I)}$  state. As shown in Figure 3, titrations with  $\text{Hg(I)}$  ions yield much lower Trp fluorescence reduction than titrations with  $\text{Hg(II)}$  ions for all three ApoE variants. It was not possible to fit a binding equation to the  $\text{Hg(I)}$  data, but the binding of  $\text{Hg(I)}$  ions appears to be weak—likely in the millimolar range. It is however possible that  $\text{Hg(I)}$  ions may not quench Trp fluorescence as efficiently as  $\text{Hg(II)}$  ions, and the  $\text{Hg(I)}$  titration results should therefore be interpreted with caution.

**3.2. CD Spectroscopy.** ApoE is previously known to be a mainly  $\alpha$ -helical protein in aqueous solutions.<sup>49,55</sup> This was confirmed by our CD measurements, where all three ApoE variants exhibit CD spectra with characteristic minima around 208 and 222 nm (Figure 4), which are typical for  $\alpha$ -helical secondary structures.<sup>55</sup> Upon titration with  $\text{Hg(II)}$  ions, the CD spectra gradually lost some intensity, although they generally maintained  $\alpha$ -helical shapes. These changes cannot be explained by dilution of the sample, as the total increase in volume during the titrations did not exceed 2%.

When titrated with  $\text{Hg(II)}$  ions, the three ApoE variants showed different intensity losses for the 208 and 222 nm minima (Figure 4 and Table 2). The  $[\theta_{222}]/[\theta_{208}]$  ratio in CD spectra has previously been shown to reflect hydrophobic coil-coil interactions of  $\alpha$ -helical secondary structures, also known as  $\alpha$ -helical supercoiling or simply superhelicity.<sup>56–58</sup> The largest increase in the  $[\theta_{222}]/[\theta_{208}]$  ratio, indicative of increased helix supercoiling upon addition of  $\text{Hg(II)}$  ions, is observed for the ApoE4 variant, which changes from 0.96 to 1.16 (Table 2). ApoE2 displays the smallest change, from 0.93 to 0.98, while ApoE3 increases from 0.99 to 1.13 (Table 2). A careful investigation of the ApoE4 CD spectra furthermore shows that the minima display small but clear changes during the titration: in the presence of 80  $\mu\text{M}$   $\text{Hg(II)}$  ions, the minima have moved from, respectively, 208.5 to 209.5 nm and from 221 to 222.5 nm (Figure 4(C1)), which is a further indication

of secondary structure alterations. All three repetitions of this titration gave the same results. For the ApoE2 variant, no such shifts were observed (Figure 4(A1)). These changes are in line with our previous observations that metal ions can promote protein supercoiling,<sup>59</sup> and also with earlier reports that  $\text{Hg(II)}$  ions can generally affect protein folding, misfolding, and aggregation.<sup>60–62</sup> A previous study showed that the ApoE C-terminal domain, which contains lipoprotein binding and ApoE self-association sites, has an intrinsic propensity to form coil-coiled interactions stabilized by salt bridges.<sup>63</sup> Thus, it is possible that the observed  $\text{Hg(II)}$ -induced structural changes take place in the C-terminal domain. Future research should be able to identify the exact location(s) of the  $\text{Hg(II)}$  binding site(s), the nature of the structural changes, and if binding of  $\text{Hg(II)}$  ions affects the protein's function(s).

Titrations with monovalent  $\text{Hg(I)}$  ions, that is, with 1 mM TCEP reducing agent added to the samples, produced much smaller changes in the CD spectra (Figure 4), indicating weaker ApoE binding affinity for  $\text{Hg(I)}$  ions than for  $\text{Hg(II)}$  ions. These results are in line with those from the fluorescence measurements (Figure 4), where  $\text{Hg(I)}$  ions for all three ApoE variants produced much weaker Trp fluorescence reduction than  $\text{Hg(II)}$  ions. However, it cannot be ruled out that the monovalent  $\text{Hg(I)}$  ions might have different binding sites and/or different binding configurations than  $\text{Hg(II)}$  ions and may therefore not induce the same structural changes as  $\text{Hg(II)}$  ions. Overall though, it appears that the  $\text{Hg(I)}$  interactions with ApoE proteins are weak and of little biological relevance. As 1 mM TCEP roughly corresponds to the reducing environment inside human cells, our results suggest that biologically relevant interactions between inorganic  $\text{Hg}$  ions and ApoE proteins will not take place intracellularly, but rather in the oxidizing extracellular environment, where the  $\text{Hg}$  ions are in their divalent  $\text{Hg(II)}$  state.

It should be noted that already before addition of the  $\text{HgCl}_2$  salt, there are slight differences in the CD spectra and in superhelicity between the three ApoE variants (Figure 4 and Table 2), indicating different secondary structures. It has previously been suggested that the ApoE variants could exhibit different secondary structures due to the mutations in positions 112 and 158. Specifically, it has been proposed that the N- and C-termini would be positioned closer to each other in ApoE4, than in ApoE2 and ApoE3, due to the interaction between Arg61 and Glu255 in ApoE4.<sup>64,65</sup> Such an interaction is considered unlikely in ApoE2 and ApoE3, where the Arg61 residue is believed to interact with Cys112 and therefore be unavailable for interactions with Glu255. Given the different initial structures, it is not surprising that addition of  $\text{Hg(II)}$  ions appears to induce somewhat different structural alterations in the three variants.

## 4. CONCLUSIONS

$\text{Hg(II)}$  ions bind all three ApoE variants with approximately the same binding affinity, around 4–5  $\mu\text{M}$  (Figure 2 and Table 1). This indicates similar binding sites with similar binding ligands in all protein variants. The residues that differ between the variants, that is, Cys112 residues in ApoE2 and ApoE3 and Cys158 in ApoE2, are therefore most likely not directly involved in  $\text{Hg(II)}$  coordination. Instead, the weaker binding to  $\text{Hg(II)}$  ions at acidic pH (Figure 2), where histidines are protonated, suggests that the His140 and His299 residues could be involved as  $\text{Hg(II)}$  binding ligands.  $\text{Hg(II)}$  binding was found to be non-cooperative, with Hill coefficients around

**Figure 4.** CD spectra showing titrations of 5  $\mu\text{M}$  ApoE protein with  $\text{HgCl}_2$  in 20 mM sodium phosphate buffer, pH 7.3 at 20  $^\circ\text{C}$ . Row A: ApoE2; row B: ApoE3; and row C: ApoE4; column 1:  $\text{Hg(II)}$  ions and column 2:  $\text{Hg(I)}$  ions (1 mM TCEP added, pink).  $\text{HgCl}_2$  was added in steps of 0  $\mu\text{M}$  (black), 2  $\mu\text{M}$  (red), 5  $\mu\text{M}$  (blue), 40  $\mu\text{M}$  (green), and 80  $\mu\text{M}$  (orange).

1, and multiple binding sites are likely present. Monovalent  $\text{Hg(I)}$  ions display much weaker binding affinities to all three ApoE variants, likely in the millimolar region (Figure 3), and induce virtually no change in the ApoE secondary structure (Figure 4). It therefore appears that the ApoE proteins do not have biologically relevant interactions with  $\text{Hg(I)}$  ions, which exist in reducing intracellular environments, but rather with  $\text{Hg(II)}$  ions, which exist in oxidizing extracellular environ-

ments. Bound  $\text{Hg(II)}$  ions induce minor but distinct structural alterations in all ApoE protein variants, interpreted as increased superhelicity and possibly located to the C-terminal domain, which contains lipoprotein binding and ApoE self-association sites and which has an intrinsic propensity to form coil-coiled interactions. The structural alterations are most pronounced in ApoE4 and least pronounced in ApoE2 (Figure 4). Thus, while the  $\text{Hg(II)}$  binding affinity is virtually the same for the three

**Table 2. Negative CD Signal Intensities [ $\theta \times 10^{-3}$ ] at 208 and 222 nm together with the Calculated [ $\theta_{222}$ ]/[ $\theta_{208}$ ] Ratios Derived from the CD Spectra Shown in Figure 3**

ApoE variants, the differences in structure induction between the three ApoE variants might conceivably be connected to the *APOE-ε4* gene being a risk factor in mercury intoxication but not the *APOE-ε2* and *APOE-ε3* genes. Future studies should clarify the binding sites for Hg(II) ions in the ApoE protein, the nature of the structural changes induced by the Hg(II) ions, and how these changes may affect the protein's function(s).

Alzheimer's disease (AD) is the most common cause of dementia worldwide. AD brains display deposits of insoluble amyloid plaques consisting mainly of aggregated amyloid- $\beta$  (A $\beta$ ) peptides, and A $\beta$  oligomers are likely a toxic species in AD pathology. AD patients display altered metal homeostasis, and AD plaques show elevated concentrations of metals such as Cu, Fe, and Zn. Yet, the metal chemistry in AD pathology remains unclear. Ni(II) ions are known to interact with A $\beta$  peptides, but the nature and effects of such interactions are unknown. Here, we use numerous biophysical methods—mainly spectroscopy and imaging techniques—to characterize A $\beta$ /Ni(II) interactions *in vitro*, for different A $\beta$  variants: A $\beta$ (1–40), A $\beta$ (1–40)(H6A, H13A, H14A), A $\beta$ (4–40), and A $\beta$ (1–42). We show for the first time that Ni(II) ions display specific binding to the N-terminal segment of full-length A $\beta$  monomers. Equimolar amounts of Ni(II) ions retard A $\beta$  aggregation and direct it towards non-structured aggregates. The His6, His13, and His14 residues are implicated as binding ligands, and the Ni(II)-A $\beta$  binding affinity is in the low  $\mu$ M range. The redox-active Ni(II) ions induce formation of dityrosine cross-links via redox chemistry, thereby creating covalent A $\beta$  dimers. In aqueous buffer Ni(II) ions promote formation of beta sheet structure in A $\beta$  monomers, while in a membrane-mimicking environment (SDS micelles) coil–coil helix interactions appear to be induced. For SDS-stabilized A $\beta$  oligomers, Ni(II) ions direct the oligomers towards larger sizes and more diverse (heterogeneous) populations. All of these structural rearrangements may be relevant for the A $\beta$  aggregation processes that are involved in AD brain pathology.

Alzheimer's disease (AD), the leading cause of dementia worldwide, is a progressive, irreversible, and currently incurable chronic neurodegenerative disorder<sup>1–3</sup>, primarily manifesting as short-term memory loss. Pathological hallmarks of AD include brain atrophy, with extensive brain deposits of amyloid plaques and neurofibrillary Tau tangles occurring years before symptom manifestation<sup>3–5</sup>. The plaques, which consist mainly of amyloid- $\beta$  (A $\beta$ ) peptides aggregated into insoluble fibrils<sup>6</sup>, display a characteristic cross- $\beta$  structure at the core of their constituent fibrils<sup>7,8</sup>. The plaques are the end-product of an aggregation process involving formation of extra- and intracellular intermediates such as neurotoxic A $\beta$  oligomers<sup>9–14</sup>. The oligomeric aggregates may spread from neuron to neuron via exosomes<sup>15,16</sup>. However, the relationship between A $\beta$  aggregation, neurodegenerative mechanisms, cognitive decline, the proposed amyloid cascade hypothesis, and disease progression is not fully understood<sup>2,13,14,17</sup>.

The 36–43 residues long A $\beta$  peptides found in the plaques are produced by enzymatic cleavage of the membrane-binding amyloid- $\beta$  precursor protein, APP<sup>18</sup>. In monomeric form, the A $\beta$  peptides are intrinsically disordered and soluble in water. The central and C-terminal segments are hydrophobic and may interact with

<sup>1</sup>Department of Biochemistry and Biophysics, Arrhenius Laboratories, Stockholm University, 106 91 Stockholm, Sweden. <sup>2</sup>Department of Chemistry and Biotechnology, Tallinn University of Technology, Tallinn, Estonia. <sup>3</sup>Department of Medical Biochemistry and Biophysics, Umeå University, 901 87 Umeå, Sweden. <sup>4</sup>The National Institute of Chemical Physics and Biophysics, Tallinn, Estonia. <sup>5</sup>Institute of Environmental Medicine, Karolinska Institutet, Nobels Väg 13, 171 77 Stockholm, Sweden. <sup>6</sup>Department of Clinical Physiology, Capio St. Görans Hospital, St. Göransplan 1, 112 19 Stockholm, Sweden. <sup>7</sup>Chemistry Section, Arrhenius Laboratories, Stockholm University, 106 91, Stockholm, Sweden. <sup>✉</sup>email: elina.berntsson@dbb.su.se; seb@student.su.se

membranes or fold into a hairpin conformation that likely is required for aggregation<sup>19</sup>. The negatively charged N-terminal segment is hydrophilic and readily interacts with metal ions and other cationic molecules<sup>20–23</sup>.

AD brains typically display altered metal homeostasis<sup>17,24,25</sup>, and AD plaques accumulate metals such as calcium (Ca), copper (Cu), iron (Fe), and zinc (Zn)<sup>26–28</sup>. Thus, dysregulated metal chemistry might be part of the AD pathology process<sup>29–32</sup>. The precursor protein APP is known to bind Cu and Zn ions<sup>33</sup>, and a possible physiological role of APP (and perhaps its fragments) might be to regulate the Cu(II) and Zn(II) concentrations in the neuronal synaptic clefts, where these ions are released in their free form<sup>34</sup> and where A $\beta$  aggregation may be initiated<sup>35</sup>. Metal ions such as Cu(II), Fe(II), Mn(II), Pb(IV) and Zn(II) have previously been shown to bind to specific A $\beta$  residues and modulate the A $\beta$  aggregation pathways<sup>20,29,36–40</sup>. Binding of metal ions, and also of other cationic molecules such as polyamines, has furthermore been reported to modulate and sometimes inhibit A $\beta$  toxicity<sup>21,22,41</sup>. However, it is unclear which possible metal interactions may be relevant for AD pathology, and which exogenous or endogenous metal ions may participate in such interactions<sup>30–32</sup>.

Nickel (Ni) is a common metal in the industrialized world, where it is used in e.g. stainless steel alloys, Ni–Cd batteries, coins, and jewelry. As a result of low-level exposure, between 10 and 20% of all people have developed some degree of contact allergy towards Ni<sup>42,43</sup>. It is therefore important to clarify the health effects of long-term Ni exposure, including potential effects on neurodegenerative diseases<sup>44</sup>. Some studies have demonstrated specific binding between Ni(II) ions and N-terminal A $\beta$  fragments, with possible effects on A $\beta$  structure and toxicity<sup>41,45–47</sup>. Yet, the interactions between pathologically relevant (i.e., full-length) A $\beta$  peptides and Ni ions are poorly explored.

In this study, we use a range of biophysical spectroscopy and imaging techniques to investigate in vitro interactions between Ni(II) ions and A $\beta$  peptides, with a focus on characterizing binding properties and effects on A $\beta$  structure and aggregation. The different A $\beta$  peptides studied include the pathologically relevant A $\beta$ (1–40), A $\beta$ (4–40), and A $\beta$ (1–42) variants, together with the A $\beta$ (1–40)(H6A, H13A, H14A) mutant. Because the A $\beta$  peptides interact with membranes<sup>48</sup>, and as membrane-disruption is a possible toxicity mechanism for A $\beta$  oligomers<sup>30</sup>, the measurements have been carried out in aqueous solution as well as in a membrane-mimetic model consisting of micelles of the SDS (sodium dodecyl sulfate) detergent<sup>49</sup>. The results are compared to previous studies of the effects of both different chemical environments and metal ion interactions on A $\beta$  peptides<sup>37,38,40,48–53</sup>.

**Biological relevance of Ni and sources of exposure.** Even though Ni function is limited in human biology<sup>54</sup>, it has been suggested as an essential element in humans<sup>55</sup>, just as it is for many human-associated bacteria<sup>56</sup> and possibly all higher plants<sup>57</sup>. Elevated Ni concentrations are however toxic to plants<sup>58</sup>. In animals, inadequate Ni amounts have shown adverse effects on nutrient absorption and metabolism<sup>59,60</sup>. Due to the abundance of Ni in many plant-based foods<sup>58,61</sup>, Ni deficiency is unlikely to occur in humans, even though only some 10% of ingested Ni is absorbed<sup>62</sup>. Ni concentrations in potable water vary between 2 and 13 mg/L with a WHO limit of 70 mg/L, which is exceeded in Ni mining regions, where Ni concentrations of 200 mg/L have been found<sup>63</sup>. Respiratory Ni exposure is related to Ni industries and fossil fuel combustion, which overall are the main global sources of Ni emissions<sup>58,62</sup>, and to cigarette smoking including e-cigarettes<sup>38,64</sup>. In addition to Ni–Cd batteries, the main industrial uses of Ni is as a whitening agent in Cu alloys for e.g. coins and jewellery, which may cause allergic contact dermatitis<sup>58</sup>, and as a provider of corrosion resistance in steel alloys for e.g. surgical tools, biomedical implants, and body piercings. One study of Ni-containing hip prosthetic devices found that Ni blood concentration rose about twofold after metal-on-metal hip arthroplasty<sup>65</sup>. Ni is also present in some formulations for dental amalgam fillings<sup>66</sup>.

The human health risks of Ni exposure are well-known and widespread, as Ni use and exposure has gradually grown from human prehistory<sup>67</sup> to modern times<sup>68</sup>. Ni is known to be haematotoxic, immunotoxic, neurotoxic, genotoxic, reproductive toxic, pulmonary toxic, nephrotoxic, hepatotoxic and carcinogenic<sup>58,69</sup>. Other pathological effects of Ni exposure in the occupational settings are rhinitis, asthma, nasal septum perforation, nasal sinus cancer, and respiratory cancer<sup>70</sup>. Ni can pass the placental barriers and accumulate in the fetus<sup>71</sup>. It can also pass the blood–brain barrier, and brain accumulation can result from high levels of exposure<sup>54</sup>. Yet, most people experience low exposure levels<sup>66</sup>, and the most common health effect is allergic reactions<sup>42,43</sup>.

The neurotoxic properties of Ni are well documented, but data on Ni in neurodegenerative disorders are scarce<sup>44</sup>. A case report of skin tissue Ni concentrations in a patient recovering from ALS after metal chelation described a Ni concentration of 850  $\mu\text{g}/\text{kg}$ <sup>72</sup>. A 44 year old ALS patient died after 9 years of heavy metal exposure in a nickel–cadmium battery factory<sup>73</sup>. Increased blood Ni concentrations have been detected in multiple sclerosis (MS) patients<sup>74</sup>, and soil Ni was found to be elevated in a Canadian MS cluster<sup>75</sup>. Recent data also indicate a possible contribution from Ni in the causation of neurodevelopmental dysfunctional states such as autism<sup>76</sup>.

As a component of tobacco, cigarette smoke, and air pollution, Ni may contribute to environmental risk factors for AD. Mice exposed to a Ni nanoparticle model of air pollution showed doubled brain levels of A $\beta$ <sub>40</sub> and A $\beta$ <sub>42</sub> within 24 h, even at a permissible limit of nickel hydroxide exposure according to occupational safety and health standards<sup>77</sup>. Another study reported higher yet not statistically significantly elevated Ni concentrations in post-mortem brain and ventricular fluid of AD patients (n = 14), compared to healthy controls (n = 15)<sup>25</sup>. A recent study reported that Ni(II) ions interfered with aggregation of the Tau protein<sup>78</sup>.

## Materials and methods

**Samples and preparations.** Ni(II) acetate and 2-(N-Morpholino)ethanesulfonic acid hydrate (MES) buffer were purchased from Sigma (Sigma/Merck KGaA, Darmstadt, Germany). The SDS detergent was bought from ICN Biomedicals Inc (USA). Sodium chloride and sodium hydroxide were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Wild-type (wt) A $\beta$ (1–42) peptides, abbreviated as A $\beta$ <sub>42</sub>, with the primary sequence DAEFR<sub>3</sub>HD<sub>5</sub>SGY<sub>10</sub>EV<sub>15</sub>HHQ<sub>15</sub>KLV<sub>20</sub>FF<sub>20</sub>AEDV<sub>25</sub>GNKGA<sub>30</sub>IIGLM<sub>35</sub>VGGV<sub>40</sub>IA, were purchased synthetically manufactured from JPT Peptide Technologies (Germany), while recombinantly produced A $\beta$ <sub>42</sub> peptides were purchased from rPeptide LLC (USA). Recombinantly produced wild-type (wt) A $\beta$ (1–40) peptides, abbreviated as A $\beta$ <sub>40</sub>, as well as N-terminal truncated A $\beta$ (4–40) peptides, were purchased as lyophilized powder from AlexoTech AB (Umeå, Sweden). The A $\beta$ <sub>40</sub> peptides were either unlabeled, uniformly <sup>15</sup>N-labeled, or uniformly <sup>13</sup>C, <sup>15</sup>N-labeled. A recombinantly produced mutant version of A $\beta$ <sub>40</sub>, where the three histidine residues H6, H13, and H14 have been replaced with alanines, i.e. A $\beta$ (1–40)(H6A, H13A, H14A) was also purchased from Alexo-Tech AB. This mutant is here abbreviated as A $\beta$ <sub>40</sub>(NoHis). All A $\beta$  variants were stored at – 80 °C until use, when they were dissolved to monomeric form before the measurements. The A $\beta$ <sub>40</sub> and A $\beta$ (4–40) peptides were then dissolved in 10 mM NaOH to 100  $\mu$ M concentration, and sonicated for 5 min in an ice-bath to dissolve possible pre-formed aggregates. Finally, buffer was added to the peptide solutions. All preparation steps were performed on ice, and the peptide concentrations were determined by weighing the dry powder and/or by NanoDrop measurements of dissolved material.

**Preparation of A $\beta$ <sub>42</sub> oligomers.** Monomeric solutions of A $\beta$ <sub>42</sub> peptides were prepared via size exclusion chromatography, according to the following procedure. First, lyophilized A $\beta$ <sub>42</sub> powder (1 mg) was dissolved in pure dimethyl sulfoxide (DMSO; 250  $\mu$ L). A solution of 5 mM NaOH (pH = 12.3) was used to equilibrate a Sephadex G-250 HiTrap desalting column (GE Healthcare, Uppsala), which was then washed with 10–15 mL of 5 mM NaOD (pD = 12.7)<sup>79</sup>. The A $\beta$ <sub>42</sub> solution in DMSO was added to the column, followed by 5 mM NaOD (1.25 mL). Peptide fractions in 5 mM NaOD were then collected on ice at a flow rate of 1 mg/mL. Ten fractions of 1 mL were collected in 1.5 mL low-binding reaction tubes. The A $\beta$ <sub>42</sub> concentration in each fraction was measured with a NanoDrop instrument (Eppendorf, Germany) at 280 nm, using a molar extinction coefficient of 1280 M<sup>-1</sup> cm<sup>-1</sup> for the single tyrosine residue in the peptide<sup>80</sup>. Liquid nitrogen was used to flash-freeze the fractions, which then were topped with argon gas, and stored at – 80 °C until use. Two well-defined sizes of SDS-stabilized A $\beta$ <sub>42</sub> oligomers—named according to the SDS concentration used: A $\beta$ O<sub>0.05%SDS</sub> (approximately dodecamers) and A $\beta$ O<sub>0.2%SDS</sub> (approximately tetramers)—were prepared using an established protocol<sup>81</sup> with the following modifications: the preparations were carried out in D<sub>2</sub>O without the original dilution step, and at a fourfold lower peptide concentration<sup>82</sup>. The reaction mixtures, consisting of 100  $\mu$ M A $\beta$ <sub>42</sub> peptide in phosphate buffered saline (PBS) buffer containing either 0.05% SDS or 0.2% SDS, which corresponds to 1.7 mM and 6.9 mM SDS, respectively, were incubated at 37 °C for 24 h together with 0–500  $\mu$ M of Ni(II) acetate. Liquid nitrogen was used to flash-freeze the prepared oligomer solutions, which then were stored at – 20 °C until further use. When thawed at room temperature for experimental analyses, the oligomers were stable for several days.

**NMR spectroscopy measurements of A $\beta$ <sub>40</sub> binding to Ni(II) ions.** 1D and 2D nuclear magnetic resonance (NMR) spectra were recorded on Bruker Avance 500 and 700 MHz spectrometers equipped with cryoprobes. First 42  $\mu$ M and then 84  $\mu$ M of Ni(II) acetate was added to 84  $\mu$ M of monomeric A $\beta$ <sub>40</sub> peptides, either <sup>13</sup>C, <sup>15</sup>N-double-labelled or <sup>15</sup>N-mono-labelled, in 20 mM sodium phosphate buffer at pH 7.3 or pH 5.6 (90/10 H<sub>2</sub>O/D<sub>2</sub>O). During the titrations, 2D <sup>1</sup>H, <sup>15</sup>N-HSQC and 2D <sup>1</sup>H, <sup>13</sup>C-HSQC spectra were recorded at 5 °C. Measurements were also conducted in the presence of 50 mM SDS detergent, at 25 °C. As the critical micelle concentration for SDS is 8.2 mM in water at 25 °C<sup>83</sup>, micelles have clearly formed under these conditions. SDS micelles are simple membrane models suitable for NMR spectroscopy due to their small size, i.e. on average 62 molecules per micelle<sup>49</sup>. Thus, there is approximately 0.8 mM of SDS micelles in the sample, i.e., around 10 $\times$  more micelles than A $\beta$ <sub>40</sub> peptides, which means that no micelle should harbour multiple A $\beta$  peptides. All NMR data were processed and evaluated using the Topspin software (v. 3.2), employing already published HSQC crosspeak assignments for A $\beta$ <sub>40</sub> in buffer<sup>84–86</sup> and in the presence of SDS micelles<sup>81</sup>.

**CD spectroscopy measurements of Ni(II)-induced changes in A $\beta$  secondary structure.** Circular dichroism (CD) was carried out in a Chirascan CD spectrometer (Applied Photophysics Ltd., U.K.) using a 2 mm quartz cuvette containing 600  $\mu$ L of A $\beta$  peptide in 20 mM phosphate buffer, pH 7.3. The studied A $\beta$  variants were A $\beta$ <sub>40</sub> (10  $\mu$ M), A $\beta$ <sub>40</sub>(NoHis) (10  $\mu$ M), and A $\beta$ (4–40) (5  $\mu$ M).

Measurements were conducted either in buffer only or with added SDS micelles. CD spectra were recorded at 25 °C between 190 and 260 nm, using steps of 0.5 nm. After the first recorded spectrum, 50 mM SDS detergent was added to some of the samples. Then, small volumes of Ni(II) acetate (2 mM and 10 mM stock solutions) were titrated to each sample, in steps of 2  $\mu$ M, 4  $\mu$ M, 16  $\mu$ M, 56  $\mu$ M, 156  $\mu$ M, 256  $\mu$ M, and finally 512  $\mu$ M. All data was processed with an eight points smoothing filter (Savitsky-Golay) using the Chirascan Pro-Data v.4.4.1 software (Applied Photophysics Ltd., U.K.).

**Binding affinity of Ni(II)-A $\beta$  complexes.** Binding affinities for Ni(II)-A $\beta$  complexes were estimated by fitting NMR and CD titration data, respectively, to Eq. (1) (the Morrison equation<sup>87</sup>):

$$I = I_0 + \frac{I_\infty - I_0}{2 * [A\beta]} * \left( (K_D + [Ni] + [A\beta]) - \sqrt{(K_D + [Ni] + [A\beta])^2 - 4 * [Ni] * [A\beta]} \right) \quad (1)$$

This equation assumes a single metal binding site, where [A $\beta$ ] is the peptide concentration, [Ni] is the concentration of the titrated Ni(II) ions, I<sub>0</sub> is the initial signal intensity, I<sub>∞</sub> is the steady-state (saturated) signal intensity at the end of the titration series, and K<sub>D</sub> is the dissociation constant for the Ni(II)-A $\beta$  complex. As no corrections for buffer conditions are done, the computed dissociation constants should be considered as apparent (K<sub>D</sub><sup>APP</sup>).

For the CD data, a binding curve was generated by plotting the CD intensity at 208 nm vs the Ni(II) concentration. For the NMR data, binding curves were generated by plotting HSQC crosspeak intensities versus Ni(II) concentration. The measured crosspeak intensities were normalized to the intensity of the V40 crosspeak for each step of added Ni(II) ions.

**A $\beta$ <sub>40</sub> aggregation kinetics monitored via ThT fluorescence measurements.** The kinetics of amyloid aggregation over time for A $\beta$ <sub>40</sub> peptides together with Ni(II) ions was monitored via measurements with a 96-well plate reader (FLUOstar Omega) of the fluorescence signal of the dye Thioflavin T (ThT), a molecular probe that displays strong fluorescence intensity when bound to amyloid material<sup>88,89</sup>. The samples contained 10  $\mu$ M A $\beta$ <sub>40</sub> peptide, 10 mM sodium phosphate buffer, pH 7.4, 40  $\mu$ M ThT dye, and 0, 1, 2.5, 5, 7.5, 10, 20, or 50  $\mu$ M of Ni(II) acetate. The peptide concentration was determined using a NanoDrop microvolume spectrophotometer. Measurements were recorded at three-minute intervals for 24 h at 37 °C, with five replicate samples per condition and excitation and emission wavelengths of 440 and 480 nm, respectively. The samples were continuously shaken (orbital mode) between the measurements. To determine the maximum growth rate and the half-time of A $\beta$  aggregation, the resulting ThT fluorescence data were fitted to a sigmoidal curve using Eq. (2)<sup>90</sup>:

$$F(t) = F_0 + \frac{A}{1 + \exp[-r_{\max}(t - t_{1/2})]} \quad (2)$$

where  $F_0$  is the baseline fluorescence intensity,  $A$  is the total increase in fluorescence intensity,  $r_{\max}$  is the maximum growth rate, and  $t_{1/2}$  is the time when half of the A $\beta$  monomers have aggregated.

**Atomic force microscopy images of A $\beta$ <sub>40</sub> aggregates.** Images of A $\beta$ <sub>40</sub> aggregates were recorded with a BioScope Catalyst (Bruker Corp., USA) atomic force microscope (AFM), operating in peak force mode in air and using MSLN and SLN cantilevers (Bruker Corp., USA). The scan rate was 0.51 Hz, with a resolution of 512 Å ~ 512 pixels. Samples of 10  $\mu$ M A $\beta$ <sub>40</sub> peptide were incubated for 24 h with either 0, 1, 10, or 50  $\mu$ M Ni(II) acetate, using the same conditions as in the ThT experiments described above. At the end of the procedure, 30  $\mu$ L samples were diluted in 30  $\mu$ L Milli-Q water and then applied on freshly prepared mica substrates. After 20 min, the mica substrates were washed three times with Milli-Q water and left to air-dry.

**Blue native polyacrylamide gel electrophoresis of A $\beta$ <sub>42</sub> oligomers.** The A $\beta$ <sub>42</sub> oligomer samples prepared with 0–500  $\mu$ M Ni(II) acetate, as described in the materials section, were analyzed with blue native polyacrylamide gel electrophoresis (BN-PAGE) using the Invitrogen electrophoresis system. First, 4–16% Bis-Tris Novex gels (ThermoFisher Scientific, USA) were loaded with A $\beta$ <sub>42</sub> oligomer samples (10  $\mu$ L) in addition to the Amersham High Molecular Weight Calibration Kit for native electrophoresis (GE Healthcare, USA). The gels were run at 4 °C according to the Invitrogen instructions (ThermoFisher Scientific, USA). Staining was done with the Pierce Silver Staining Kit (ThermoFisher Scientific, USA).

**Infrared spectroscopy.** Fourier-transformed infrared (FTIR) spectra of the A $\beta$ <sub>42</sub> oligomers prepared with 0–500  $\mu$ M Ni(II) acetate, as described in the materials section, were recorded on a Tensor 37 FTIR spectrometer (Bruker Optics, Germany) operating in transmission mode at room temperature and equipped with a liquid nitrogen-cooled MeCdTe detector and a sample shutter. During the measurements, the instrument was continuously purged with dry air. 8–10  $\mu$ L of the 80  $\mu$ M A $\beta$ <sub>42</sub> oligomer samples were placed between two flat CaF<sub>2</sub> discs, which were separated by a 50  $\mu$ m plastic spacer that had been covered with vacuum grease at the periphery. The mounted IR cuvette was put in a holder inside the sample chamber, and was then allowed to sit for at least 20 min after the chamber lid was closed, to remove H<sub>2</sub>O vapor. FTIR spectra were recorded between 1900 and 800  $\text{cm}^{-1}$ , at a resolution of 2  $\text{cm}^{-1}$  and with 6 mm aperture. The IR intensity above 2200  $\text{cm}^{-1}$  was blocked with a germanium filter, and that below 1500  $\text{cm}^{-1}$  with a cellulose membrane, to increase the light intensity in the relevant spectral range<sup>91</sup>. The OPUS 5.5 software was used for analysis and plotting of the spectra. Second derivatives were computed with a smoothing factor of 17.

**Fluorescence measurements of Ni(II)-induced formation of dityrosine in A $\beta$ <sub>40</sub>.** A Jobin Yvon Horiba Fluorolog 3 fluorescence spectrometer (Longjumeau, France) was used to record fluorescence emission spectra between 330 and 500 nm (excitation at 315 nm) at room temperature of 10  $\mu$ M A $\beta$ <sub>40</sub> peptide dissolved in 20 mM MES buffer, pH 7.3. The samples were put in a quartz cuvette with 4 mm path length (volume 1 mL). To investigate the effect of Ni(II) ions on dityrosine formation, one sample contained 100  $\mu$ M Ni(II) acetate. The control sample contained 50  $\mu$ M of the chelator EDTA, to remove possible free metal ions. Spectra were recorded after 0 and 6 h of incubation, where the sample was kept at room temperature without agitation or other treatment. All experiments were conducted in triplicate, and before the final measurement, 300  $\mu$ M of EDTA was added to the sample to remove metal ions.

## Results

**NMR spectroscopy: molecular details of Ni(II) binding to the A $\beta$ <sub>40</sub> monomer.** High-resolution NMR experiments were conducted to investigate possible residue-specific molecular interactions between Ni(II) ions and monomeric A $\beta$ <sub>40</sub> peptides. Figures 1 and 2 show 2D <sup>1</sup>H,<sup>15</sup>N-HSQC spectra for the amide crosspeak region for 84  $\mu$ M <sup>13</sup>C,<sup>15</sup>N-labeled A $\beta$ <sub>40</sub> peptides at either pH 7.3 or pH 5.6, recorded before and after addition of first 42  $\mu$ M and then 84  $\mu$ M Ni(II) acetate, i.e. Ni(II):A $\beta$ <sub>40</sub> ratios of respectively 1:2 and 1:1. Similar measure-

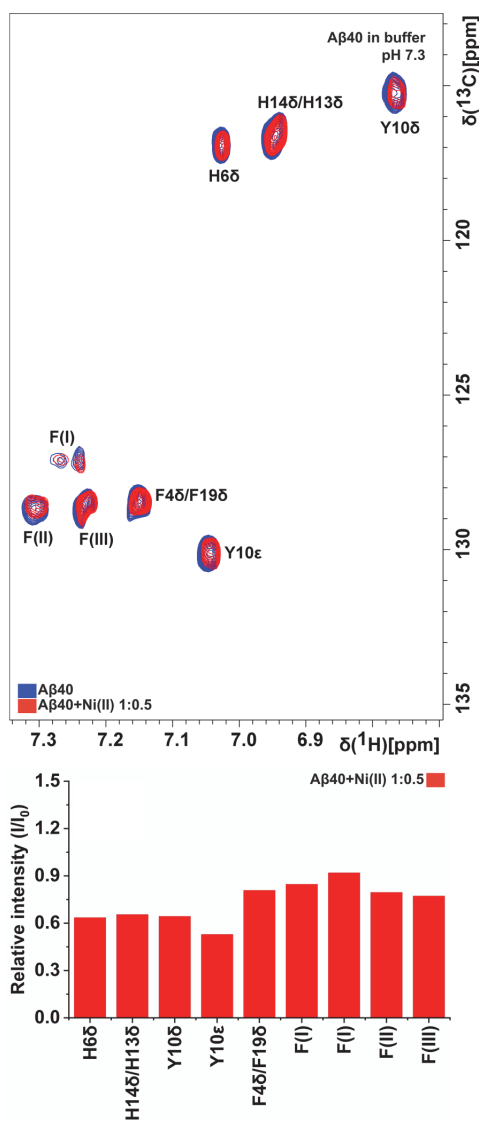

**Figure 1.** NMR 2D  $^1\text{H}$ ,  $^{15}\text{N}$ -HSQC-spectra of 84  $\mu\text{M}$   $^{15}\text{N}$ -labeled  $\text{A}\beta_{40}$  peptides before (blue peaks) and after addition of first 42  $\mu\text{M}$  (red peaks) and then 84  $\mu\text{M}$  (teal peaks)  $\text{Ni}(\text{II})$  acetate. Spectra were recorded at 5  $^\circ\text{C}$  in 20 mM sodium phosphate buffer at pH 7.3 (A), at pH 5.6 (B), and at pH 7.3 together with 50 mM SDS detergent (C). The peak intensity in the bar charts is given as the ratio between the crosspeak intensity with added  $\text{Ni}(\text{II})$  ions relative to the intensity before addition of  $\text{Ni}(\text{II})$  ions, i.e.  $I/I_0$ .

ments were conducted also for  $\text{A}\beta_{40}$  peptides together with SDS micelles (50 mM SDS detergent concentration) at pH 7.3 (Fig. 1C).

For  $\text{A}\beta_{40}$  in aqueous pH 7.3 buffer, addition of  $\text{Ni}(\text{II})$  ions induces a concentration-dependent loss of amide crosspeak intensity, especially in the N-terminal region (Fig. 1A). This indicates specific binding of  $\text{Ni}(\text{II})$  ions to N-terminal  $\text{A}\beta_{40}$  residues. The specific loss of N-terminal crosspeak intensity is likely caused by intermediate or even slow (on the NMR time-scale) chemical exchange between a free and a bound state of the  $\text{A}\beta_{40}$  peptides, similar to the effect induced by  $\text{Cu}(\text{II})$  and  $\text{Zn}(\text{II})$  ions<sup>40,92</sup>, probably together with paramagnetic quenching effects of the  $\text{Ni}(\text{II})$  ions<sup>93</sup>. When the  $\text{Ni}(\text{II})$  ions are added to the sample, no new crosspeaks corresponding to  $\text{Ni}(\text{II})$ -bound  $\text{A}\beta_{40}$  peptides are observed (Fig. 1A). This suggests that no single well-defined  $\text{Ni}(\text{II})$ - $\text{A}\beta_{40}$  complex exists. Instead, a range of  $\text{Ni}(\text{II})$ -bound states of the  $\text{A}\beta_{40}$  peptides are likely present, probably at different stages of aggregation and oligomerization. Each state is then too weakly populated to create distinct NMR crosspeaks. This is in line with earlier NMR studies reporting that  $\text{A}\beta_{40}$  peptides are in a dynamic exchange between NMR-observable monomers and heterogeneous NMR-invisible oligomers (a “dark state”)<sup>92,94</sup>.

There is also a general loss of crosspeak intensity for all  $\text{A}\beta_{40}$  residues, including the central and C-terminal amino acids, upon addition of  $\text{Ni}(\text{II})$  acetate. This effect is likely caused by a combination of non-specific  $\text{Ni}(\text{II})$  binding interactions, on an intermediate or slow NMR time-scale, and by the  $\text{Ni}(\text{II})$  ions promoting aggregation of the  $\text{A}\beta_{40}$  peptides into complexes that are too large to be observed with HSQC NMR, or they may simply precipitate out of the solution.

At pH 5.6, the loss of crosspeak intensity after added  $\text{Ni}(\text{II})$  ions is very uniform, i.e., there is no residue-specific binding (Fig. 1B). The main difference at this lower pH is that histidine residues are protonated, as they have pKa values around 6.8 in short peptides<sup>95</sup>. Naturally, protonated His residues are less prone to bind cationic metal ions. The loss of residue-specific  $\text{Ni}(\text{II})$  ion binding at pH 5.6 therefore indicates that histidines are involved in the observed residue-specific  $\text{Ni}(\text{II})$  ion binding at neutral pH. This is supported by the NMR results at pH 7.3 for the  $\text{A}\beta_{40}$  aromatic side chains, where the aromatic rings of the N-terminal residues His6, His13,

**Figure 2.** NMR 2D  $^1\text{H}$ ,  $^{13}\text{C}$ -HSQC spectra of  $84\ \mu\text{M}$   $^{13}\text{C}$ ,  $^{15}\text{N}$ -labeled  $\text{A}\beta_{40}$  peptides in 20 mM phosphate buffer, pH 7.3, before (blue) and after (red) addition of  $42\ \mu\text{M}$  Ni(II) acetate. Some Phe crosspeaks could not be assigned to individual residues, and are instead listed as F(I), F(II), and F(III).

and His14, together with Tyr10, display a somewhat larger loss of crosspeak signal intensity than the aromatic rings of the Phe4, Phe19, and Phe20 residues (Fig. 2).

Specific loss of crosspeak intensity for N-terminal residues, upon addition of Ni(II) acetate, is observed also for  $\text{A}\beta_{40}$  peptides positioned in SDS micelles (Fig. 1C), which constitute a simple model for bio-membranes<sup>48,49</sup>. The central and C-terminal  $\text{A}\beta$  regions are known to insert themselves as  $\alpha$ -helices into SDS micelles<sup>48,51</sup>, and thus, the  $^1\text{H}$ ,  $^{15}\text{N}$ -HSQC spectrum for  $\text{A}\beta_{40}$  in SDS micelles corresponds to an  $\alpha$ -helical conformation of the  $\text{A}\beta$  peptide. The N-terminal segment is known to remain unstructured outside the micelle surface, where it is available for interactions with e.g. metal ions<sup>50</sup>. The C-terminal residues are unaffected by the added Ni(II) ions (Fig. 1C), which shows that they are neither affected by direct Ni(II)-binding, nor by Ni(II)-induced aggregation—most likely  $\text{A}\beta$  peptides cannot aggregate when bound to SDS micelles, at least when there is on average

**Figure 3.** CD spectra of Ni(II) acetate titrated to A $\beta$  peptides in 20 mM phosphate buffer, pH 7.3, at 25 °C. The titrations were conducted either in the presence of SDS micelles (A–C) or in aqueous buffer only (D–F), for three different peptide variants, i.e. 10  $\mu$ M A $\beta_{40}$  (A,D), 10  $\mu$ M A $\beta_{40}$ (NoHis) (B,E), and 5  $\mu$ M A $\beta$ (4–40) (C,F). The black spectra show A $\beta$  peptides in buffer only. For samples A–C, 50 mM SDS was then added (red spectra). Next, for all samples, Ni(II) acetate was titrated in steps of 2  $\mu$ M (orange), 4  $\mu$ M (yellow), 16  $\mu$ M (turquoise), 56  $\mu$ M (green), 156  $\mu$ M (purple), and finally 256  $\mu$ M (blue spectra).

less than one peptide per micelle. Thus, also in the presence of SDS micelles (Fig. 1C), the NMR spectrum reflects Ni(II) ion binding to monomeric A $\beta_{40}$  peptides.

**CD spectroscopy measurements of A $\beta$  secondary structure.** CD spectroscopy was used to investigate possible changes in A $\beta$  secondary structure upon addition of Ni(II) ions, both in aqueous buffer and in a membrane-mimetic environment (i.e., SDS micelles). The three peptide variants A $\beta_{40}$ , A $\beta_{40}$ (NoHis) mutant, and A $\beta$ (4–40) were investigated. In aqueous buffer, the CD spectra for monomers of all three variants display typical random coil signals with minima around 196–198 nm (Fig. 3).

Addition of Ni(II) ions to A $\beta$  peptides in aqueous buffer induces concentration-dependent changes in the CD spectra for the monomers of all three peptide variants (Fig. 3D–F). For the A $\beta_{40}$ (NoHis) peptide, these changes

**Table 1.** CD signal intensities at 208 nm and 222 nm for the three  $\text{A}\beta$  variants  $\text{A}\beta_{40}$ ,  $\text{A}\beta_{40}(\text{NoHis})$ , and  $\text{A}\beta(4-40)$ , as a function of added Ni(II) acetate.

correspond to a decrease in intensity, without changing the shape of the spectrum (Fig. 3). This likely means that the Ni(II) ions induce peptide aggregation and precipitation, thereby reducing the effective  $\text{A}\beta$  concentration in the solution.

For the  $\text{A}\beta_{40}$  and  $\text{A}\beta(4-40)$  variants, addition of Ni(II) ions induces structural transitions between two distinct conformations, as evidenced by the isodichroic points around 210 nm (Fig. 3D,F).  $\text{A}\beta$  peptides in solution are known to contain some polyproline II (PPII) helix structure, especially at low temperatures<sup>50</sup>. The loss of signal intensity around 196–198 nm, and the isodichroic points around 210 nm, might be compatible with a conversion of PPII helix into random coil structure<sup>50,97,98</sup>. However, the difference spectra created by subtracting the CD spectra with no added Ni(II) acetate from those with 256  $\mu\text{M}$  Ni(II) acetate, shown in Supp. Fig. S1, clearly correspond to  $\beta$ -sheet secondary structure<sup>99</sup>. Formation of  $\beta$ -sheets upon addition of Ni(II) ions is supported also by the IR spectra shown in Supp. Fig. S2. We therefore conclude that Ni(II) ions induce  $\beta$ -sheet structure in  $\text{A}\beta_{40}$  and  $\text{A}\beta(4-40)$  peptides, in aqueous solution at neutral pH.

When SDS micelles were added to the three peptide variants, all of them adopted  $\alpha$ -helical secondary structures, producing CD signals with characteristic minima around 208 and 222 nm (Fig. 3A–C). This is consistent with previous studies reporting that  $\text{A}\beta$  peptides adopt  $\alpha$ -helical conformations in membrane-like environments, at least when there is on average less than one peptide per micelle<sup>48,49,51,96,100</sup>. The  $\text{A}\beta_{40}(\text{NoHis})$  variant, where the three His residues have been replaced with alanines, displays the strongest  $\alpha$ -helical CD signal after addition of SDS, compared to the intensity of the  $\text{A}\beta_{40}(\text{NoHis})$  random coil signal before adding SDS (Fig. 3). This is reasonable given the strong propensity of alanines to form  $\alpha$ -helices<sup>101</sup>. The  $\text{A}\beta(4-40)$  peptide also shows a relatively strong  $\alpha$ -helical CD signal, compared to the  $\text{A}\beta(4-40)$  random coil intensity before added SDS. This might be related to a lack of  $\alpha$ -helical structure<sup>51</sup> in the first three residues of  $\text{A}\beta_{40}$ , which are missing in the  $\text{A}\beta(4-40)$  variant.

Addition of Ni(II) ions induces a concentration-dependent loss of CD signal around 208 nm, but not around 222 nm, for the  $\text{A}\beta_{40}$  and the  $\text{A}\beta(4-40)$  peptides, although not for the  $\text{A}\beta_{40}(\text{NoHis})$  mutant (Fig. 3). As the 222 nm signal intensity remains approximately constant, the observed spectral changes do not correspond to a general loss of  $\alpha$ -helicity but may rather be due to a change in helix supercoiling, i.e. when two or more  $\alpha$ -helices form coiled coils via hydrophobic interactions<sup>102–104</sup>. The degree of helix supercoiling is known to be reflected by the  $[\theta_{222}]/[\theta_{208}]$  ratio, where ratios close to 1 reflect large amounts of superhelicity<sup>105</sup>. During the titrations with Ni(II) acetate the  $[\theta_{222}]/[\theta_{208}]$  ratio increases from 0.70 to 0.89 for  $\text{A}\beta_{40}$ , and from 0.75 to 1.03 for the  $\text{A}\beta(4-40)$  variant (Table 1). In both cases this would correspond to a significant increase in superhelicity. Such metal-induced changes of  $\text{A}\beta$  superhelicity, in a membrane environment, has previously been reported to be induced by Cu(II) ions<sup>96</sup>. The lack of any Ni(II)-induced structural effects in the  $\text{A}\beta_{40}(\text{NoHis})$  mutant (Fig. 3; Table 1) appears to support Ni(II) binding to  $\text{A}\beta$  via the His residues. But it is also possible that the His residues are necessary for forming a coiled-coil  $\text{A}\beta$  structure.

**Estimates of  $\text{A}\beta$ -Ni(II) binding affinity.** Ni(II)- $\text{A}\beta$  binding curves were generated by plotting crosspeak intensities from the NMR titrations (Fig. 1A) and 208 nm intensities from the CD titrations (Table 1) versus Ni(II) concentration (Fig. 4). Fitting Eq. (1) to these curves yields apparent dissociation constants ( $K_D$ ) for the Ni(II)- $\text{A}\beta$  complexes.

For the CD data (Fig. 4D,E), the signal intensities have been normalized to the first value in each titration series, i.e. the signal intensity without added Ni(II) ions. The derived  $K_D$  values are 7.8  $\mu\text{M}$  for binding to  $\text{A}\beta_{40}$ , and 17.2  $\mu\text{M}$  for binding to the  $\text{A}\beta(4-40)$  variant. These  $K_D$  values should however only be considered as approximations, as there may not be a direct correlation between Ni(II) binding and the structural changes observed in the CD spectra (Fig. 3). Our NMR measurements (Fig. 1C) confirm earlier studies showing that the N-terminal  $\text{A}\beta$  segment is free to interact with metal ions also when the central and C-terminal  $\text{A}\beta$  segments are inserted into SDS micelles<sup>48,51,96</sup>. Yet, earlier studies with Cu(II) ions have shown that the binding affinity for metal ions is reduced when the central  $\text{A}\beta$  segment is bound to some other entity<sup>106</sup>, although this effect appears to be minor for SDS micelles<sup>96</sup>.

For the NMR data, each crosspeak in Fig. 1A generates one binding curve. However, the Ni(II)-induced loss of crosspeak intensity is not only related to concentration-dependent chemical exchange, on an intermediate NMR

**Figure 4.** Binding curves for Ni(II)-Aβ complexes, derived from the NMR data in Fig. 1A and the CD data in Fig. 3A,C, respectively. The NMR and CD signal intensities are given as the ratio between the intensity with added Ni(II) ions relative to the intensity before addition of Ni(II) ions, i.e.  $I/I_0$ . Apparent binding affinities were obtained by fitting Eq. (1) to the curves. (A–C) NMR crosspeak intensity vs Ni(II) concentration for three of the crosspeaks/residues in Fig. 1A, i.e. for 84 μM Aβ<sub>40</sub> in 20 mM sodium phosphate buffer, pH 7.3 at 5 °C. (D,E) CD intensity at 208 nm vs Ni(II) concentration for the CD data in Fig. 3A,C, i.e. for 10 μM Aβ<sub>40</sub> (D) and 5 μM Aβ(4–40) (E) in 20 mM phosphate buffer, pH 7.3 at 25 °C.

**Figure 5.** ThT kinetic time curves for aggregation of 10 μM Aβ<sub>40</sub>, in 10 mM sodium phosphate buffer, pH 7.4, together with different concentrations of Ni(II) acetate: 0 μM (black), 1 μM (red), 2.5 μM (azure blue), 5 μM (magenta), 7.5 μM (green), 10 μM (navy blue), 20 μM (yellow), and 50 μM (orange). The solid lines show curves fitted with Eq. (2) to the ThT data sets.

time-scale, but also to Ni(II)-induced peptide aggregation and paramagnetic quenching of the NMR signal. Even though these effects are somewhat mitigated by normalizing the crosspeak intensity values to the V40 crosspeak intensity, for each titration step (thereby obtaining the relative intensity scale used in Fig. 4A–C), the derived  $K_D$  values should only be considered as rough approximations. The binding curves shown in Fig. 4A–C correspond to the three Aβ<sub>40</sub> crosspeaks that display the strongest apparent binding, with  $K_D$  values of respectively 5.3 μM, 6.7 μM, and 7.0 μM. These values are very similar to the apparent  $K_D$  value of 7.8 μM derived for Aβ<sub>40</sub> from the CD measurements (Fig. 4D), but they should still only be regarded as lower limits for the true  $K_D$  value. Thus, we conclude that the binding affinity for the Aβ<sub>40</sub>-Ni(II) complex is in the low μM range.

**Effects of Ni(II) ions on Aβ<sub>40</sub> aggregation kinetics.** To investigate the influence of Ni(II) ions on Aβ<sub>40</sub> aggregation, samples of 10 μM Aβ<sub>40</sub> were incubated for 24 h in the absence or presence of increasing concentrations of Ni(II) acetate. The resulting ThT curves are shown in Fig. 5, and the  $r_{max}$ ,  $t_{1/2}$ , and A parameters obtained from fitting the curves to Eq. (2) are shown in Table 2. For sub-stoichiometric Ni(II):Aβ<sub>40</sub> ratios, the Ni(II) ions

Ni(II)	0 $\mu\text{M}$	1 $\mu\text{M}$	2.5 $\mu\text{M}$	5 $\mu\text{M}$	7.5 $\mu\text{M}$	10 $\mu\text{M}$	20 $\mu\text{M}$	50 $\mu\text{M}$

$t_{1/2}$ [h]	$8.3 \pm 1.5$	$10.2 \pm 0.3$	$11.8 \pm 1.2$	$11.2 \pm 0.7$	$12.5 \pm 0.5$	$13.5 \pm 1.4$	n/a	n/a
A	$4115 \pm 436$	$2967 \pm 238$	$2085 \pm 575$	$1449 \pm 480$	$1511 \pm 132$	$1803 \pm 442$	n/a	n/a

**Table 2.** Parameters  $r_{\text{max}}$ ,  $t_{1/2}$ , and A for aggregation of 10  $\mu\text{M}$   $\text{A}\beta_{40}$  in the presence of different concentrations of Ni(II) acetate. The parameters were obtained from sigmoidal curve-fitting (Eq. 2) to the ThT curves shown in Fig. 5.

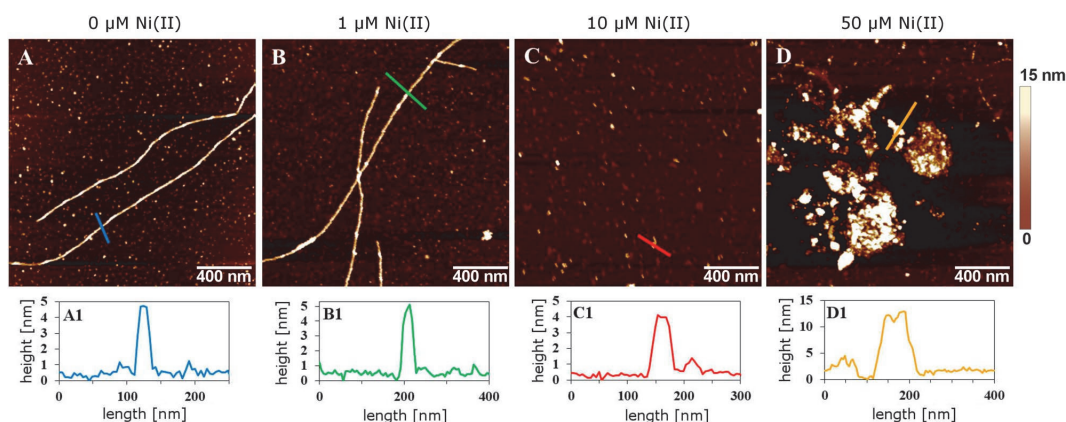

slow down the  $\text{A}\beta_{40}$  aggregation kinetics in a concentration-dependent manner. The aggregation half-time ( $t_{1/2}$ ) increases with increasing Ni(II) concentrations, i.e. from around 8 h without Ni(II) ions to over 13 h with 10  $\mu\text{M}$  Ni(II) ions. The maximum aggregation rate  $r_{\text{max}}$  shows no systematic change with increasing Ni(II) concentration, instead it fluctuates around  $0.9 \text{ h}^{-1}$  to  $1 \text{ h}^{-1}$  (Table 2). The end-point ThT fluorescence intensities (parameter “A” in Eq. 2) generally decrease with increasing Ni(II) concentrations (Fig. 5), suggesting that less amyloid material (ThT-binding aggregates) is formed when Ni(II) ions are present. Other explanations are however possible, such as binding competition between ThT molecules and Ni(II) ions, or formation of very large  $\text{A}\beta$  aggregates that may block the transmitted light, or simply precipitate out of the solution. For the samples with high Ni(II) concentrations, i.e. 20  $\mu\text{M}$  and 50  $\mu\text{M}$ , above the stoichiometric Ni(II): $\text{A}\beta_{40}$  ratio, the ThT curves first increase but then decrease back towards the starting value (Fig. 5). Our best explanation for this unusual behaviour is formation of large samples that precipitate, thereby effectively reducing the  $\text{A}\beta_{40}$  concentration in the sample. It was not possible to fit Eq. (2) to these data curves.

**AFM imaging: effects of Ni(II) ions on the morphology of  $\text{A}\beta_{40}$  aggregates.** To further characterize the influence of Ni(II) ions on  $\text{A}\beta_{40}$  fibril morphology, AFM images were recorded on  $\text{A}\beta_{40}$  aggregates formed after 24 h incubation in the presence and the absence of Ni(II) (Fig. 6). Without Ni(II) acetate, 10  $\mu\text{M}$   $\text{A}\beta_{40}$  formed typical amyloid fibrils with an apparent height around 4–5 nm (Fig. 2A), which is in line with previously published work on  $\text{A}\beta$  fibrils formed in vitro<sup>107–109</sup>. A similar apparent height was observed in the presence of 1  $\mu\text{M}$  Ni(II) ions (Fig. 6B). The presence of 10  $\mu\text{M}$  Ni(II) ions, i.e. a 1:1 Ni(II): $\text{A}\beta_{40}$  ratio, significantly reduces fibril formation: only occasional very short  $\text{A}\beta_{40}$  fibril fragments were observed, which display the same height as the fibrils formed by  $\text{A}\beta_{40}$  alone (Fig. 6C). In the presence of 50  $\mu\text{M}$  Ni(II) ions no fibrils were present, but instead amorphous clumps of  $\text{A}\beta_{40}$  aggregates with variable heights around 13 nm (Fig. 6D). These results are consistent with the concentration-dependent effects of Ni(II) acetate on the  $\text{A}\beta_{40}$  aggregation process observed with the ThT measurements (Fig. 5).

**Influence of Ni(II) ions on  $\text{A}\beta_{42}$  oligomer formation.** PAGE analysis was used to investigate the effect of Ni(II) ions on the formation of  $\text{A}\beta_{42}$  oligomers, using a previously published protocol for formation of stable and homogeneous  $\text{A}\beta_{42}$  oligomers together with SDS detergent<sup>81,82</sup>. While most of the current study investigates variants of the  $\text{A}\beta_{40}$  peptide, oligomers of  $\text{A}\beta_{40}$  are not stable and therefore not suitable model systems. Thus, SEC-purified monomeric solutions of synthetic  $\text{A}\beta_{42}$  peptides were mixed with low concentrations of SDS, i.e., below the critical micelle concentration. Incubation of  $\text{A}\beta_{42}$  with 0.2% SDS (6.9 mM) leads to formation of mostly tetrameric oligomers ( $\text{A}\beta\text{O}_{0.2\% \text{SDS}}$ ), while incubation with 0.05% SDS (1.7 mM) produces larger oligomers—predominantly dodecamers ( $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$ )<sup>81</sup> (Fig. 7, lanes 2 and 6). Figure 7 also shows the effect of different Ni(II) concentrations on oligomer formation. In the absence of Ni(II) ions, the  $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$  (Lane 2) and  $\text{A}\beta\text{O}_{0.2\% \text{SDS}}$  (Lane 6) oligomers are the dominating species in their respective lanes. With increasing Ni(II) concentration, the band intensity for the major oligomeric structure declines in both cases, while smears towards higher molecular weights appear (Fig. 7, Lanes 3–5 and 7–9). Formation of  $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$  is largely disrupted when Ni(II) ions are present at 500  $\mu\text{M}$  concentration ( $\text{A}\beta_{42}$ :Ni(II) molar ratio of 1:5), while the smear extends over almost the entire length of the lane (Fig. 7, Lane 5). A similar, but less drastic effect is observed for the smaller  $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$  (Fig. 7, Lane 9). For both types of SDS-stabilized oligomers, Ni(II) ion concentrations above ~100  $\mu\text{M}$  disrupt oligomer formation and more heterogeneous  $\text{A}\beta_{42}$  oligomeric solutions containing larger oligomers are produced. A similar smearing effect of Ni(II) ions on the formation of SDS-stabilized  $\text{A}\beta_{42}$  oligomers was observed also by SDS-PAGE experiments. These results are shown and discussed in the supplementary information (Fig. S3).

**FTIR spectroscopy of  $\text{A}\beta_{42}$  oligomers formed in the presence of Ni(II) ions.** FTIR spectroscopy is a powerful technique for studying the secondary structure of proteins<sup>110–116</sup>, and can be used to characterize the backbone conformation for different aggregation states of amyloid proteins, including  $\text{A}\beta$  peptides<sup>117–119</sup>. Here, the effects of Ni(II) ions on the secondary structures of both  $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$  and  $\text{A}\beta\text{O}_{0.2\% \text{SDS}}$  oligomers were studied with transmission mode FTIR spectroscopy, using a  $\text{D}_2\text{O}$ -based buffer. The results are presented in Fig. 8 as second derivatives of IR absorption spectra, where negative bands indicate the component bands of the absorption spectra. The respective absorbance spectra are shown in Fig. S4 of the Supplementary Information.

For both types of  $\text{A}\beta_{42}$  oligomers, two bands are resolved in the amide I region (i.e., 1700–1600  $\text{cm}^{-1}$ ): a high intensity, low wavenumber band around 1630  $\text{cm}^{-1}$  (the main band for  $\beta$ -sheet structure), and a low intensity, high wavenumber band at 1685  $\text{cm}^{-1}$ . This pattern with a split double-band in the amide I region is routinely

**Figure 6.** Top row: AFM images of the aggregation products obtained after incubation of 10  $\mu\text{M}$   $\text{A}\beta_{40}$  peptides for 24 h together with either 0, 1, 10, or 50  $\mu\text{M}$   $\text{Ni(II)}$  acetate. Bottom row: Representative AFM cross-sections of respectively  $\text{A}\beta_{40}$  amyloid fibrils (A,B) and  $\text{A}\beta_{40}$  unstructured aggregates (C,D), corresponding to the colored lines shown in the AFM images.

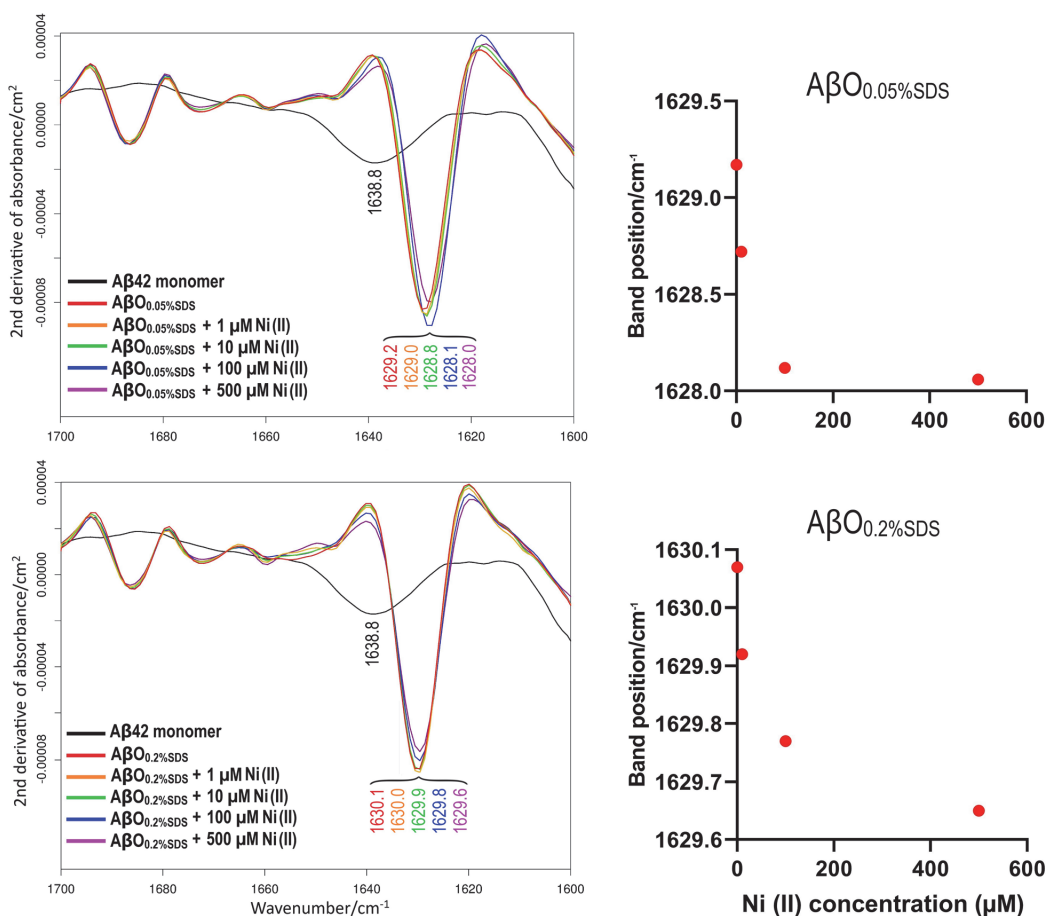

**Figure 7.** Effects of  $\text{Ni(II)}$  ions on formation of SDS-stabilized  $\text{A}\beta_{42}$  oligomers ( $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$  and  $\text{A}\beta\text{O}_{0.2\% \text{SDS}}$ ) studied by BN-PAGE. Lane 1: Monomers; Lanes 2–5:  $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$  oligomers with respectively 0, 10, 100, and 500  $\mu\text{M}$   $\text{Ni(II)}$  ions; Lanes 6–9:  $\text{A}\beta\text{O}_{0.2\% \text{SDS}}$  oligomers with respectively 0, 10, 100, and 500  $\mu\text{M}$   $\text{Ni(II)}$  ions.

considered as indicative of the anti-parallel  $\beta$ -sheet structure<sup>117,118,120</sup>. When  $\text{Ni(II)}$  acetate is introduced during the  $\text{A}\beta_{42}$  oligomer formation reactions, the main band is slightly down-shifted: for  $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$  (Fig. 8, upper row) from 1629.2  $\text{cm}^{-1}$  in the absence of  $\text{Ni(II)}$  acetate to 1628.0  $\text{cm}^{-1}$  at 500  $\mu\text{M}$  of  $\text{Ni(II)}$  acetate (the highest concentration), and for  $\text{A}\beta\text{O}_{0.2\% \text{SDS}}$  (Fig. 8, lower row) from 1630.1 to 1629.6  $\text{cm}^{-1}$  upon addition of  $\text{Ni(II)}$  acetate up to 500  $\mu\text{M}$ . The downshift is smaller for the oligomers prepared at the higher SDS concentration, indicating that they are less sensitive to  $\text{Ni(II)}$ -induced effects on the oligomer conformation. The spectral changes observed with  $\text{Ni(II)}$  are in interesting contrast to the absence of spectral effects upon addition of  $\text{Li(I)}$  ions<sup>121</sup>. The downshift is mainly observed in the presence of  $\text{Ni(II)}$  concentrations between 10 and 100  $\mu\text{M}$ , which agrees with the binding affinities estimated from the CD and NMR results. Detailed analysis of the spectra in Fig. 8 shows that the shifts in band position are associated with a widening of the main  $\beta$ -sheet band on its low wavenumber side, indicating a higher abundance of larger oligomers<sup>82</sup>. Most of this widening occurs between 10 and 100  $\mu\text{M}$   $\text{Ni(II)}$ . It further increases between 100 and 500  $\mu\text{M}$   $\text{Ni(II)}$ , which correlates with the appearance of a high molecular weight smear on the BN-PAGE gel (Fig. 7).

Our previous study on the IR characterization of  $\text{A}\beta_{42}$  oligomers has revealed a relationship between oligomer size and position of the main band in the amide I region<sup>82</sup>. According to these findings, the downshift of the main IR band is associated with an increase in average oligomer size and a concomitant extension of their  $\beta$ -sheet structure. However, the  $\text{Ni(II)}$ -induced size change is rather modest. The band position of  $\text{A}\beta\text{O}_{0.2\% \text{SDS}}$  at the highest  $\text{Ni(II)}$  ion concentration is still higher than the  $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$  band position in the absence of  $\text{Ni(II)}$  ions, indicating that the oligomers contain less than twelve peptides. Also, the band position of  $\text{A}\beta\text{O}_{0.05\% \text{SDS}}$  at 500  $\mu\text{M}$   $\text{Ni(II)}$  concentration is considerably higher than that of oligomers formed in the absence of SDS (1623.1  $\text{cm}^{-1}$ ),

**Figure 8.** Transmission FTIR data for synthetic AβO<sub>0.05%SDS</sub> (upper row) and synthetic AβO<sub>0.2%SDS</sub> (lower row) formed in the presence of different concentrations of Ni(II) ions. The spectra show raw data without normalization. Left: Second derivatives of IR absorbance spectra in the amide I range (1700–1600 cm<sup>-1</sup>) at zero Ni(II) (red); 1 μM Ni(II) (orange); 10 μM Ni(II) (green); 100 μM Ni(II) (blue); 500 μM Ni(II) (violet). The black spectrum is for Aβ<sub>42</sub> monomers. Right: Dependence on Ni(II) ion concentration for the position (in cm<sup>-1</sup>) of the main amide I band. For a more clear presentation, the data point at 1 μM was omitted.

which had an average molecular weight of ~100 kDa according to Western blotting<sup>82</sup>. Thus, the dominant β-sheet containing oligomer species of AβO<sub>0.05%SDS</sub> seem to be smaller than ~100 kDa.

The interpretation of the current IR results is in good agreement with the results from the gel electrophoresis experiments, particularly with the BN-PAGE data (Fig. 7). Both IR and PAGE results indicate that addition of Ni(II) ions appears to interfere with the SDS-induced conversion of Aβ<sub>42</sub> monomers into homogeneous and stable oligomeric structures, instead favoring formation of larger and more diverse (heterogeneous) oligomer populations.

**Ni(II)-induced dityrosine formation.** Fluorescence measurements were carried out to investigate if binding of Ni(II) ions could induce formation of covalent dityrosine crosslinks in Aβ peptides, similar to what has been observed for Cu(II) ions<sup>122–125</sup>. Fluorescence emission spectra for Aβ<sub>40</sub> peptides incubated over time with or without Ni(II) acetate are shown in Fig. 9.

The control sample without added Ni(II) ions, which contained 50 μM EDTA to ensure no free metal ions were present, displayed virtually identical spectra before and after 6 h of incubation (Fig. 9A). This is in stark contrast to the sample with 100 μM Ni(II) ions added, where two large new peaks around 410 nm and 435 nm formed during the incubation time (Fig. 9B). The peak around 410 nm is from dityrosine<sup>126</sup>, while the peak around 435 nm likely is from a different but related system, such as excimers<sup>127</sup>. These results are not surprising, as nickel is known to be very redox-active. Both the Ni(I)/Ni(II) and Ni(II)/Ni(III) redox pairs could be

**Figure 9.** Fluorescence spectra of 10  $\mu\text{M}$   $\text{A}\beta_{40}$  in 20 mM MES buffer, pH 7.3, incubated together with 50  $\mu\text{M}$  EDTA (A) or with 100  $\mu\text{M}$  Ni(II) acetate (B). Black line—0 h; red line—6 h.

involved in generating the oxygen radicals required for dityrosine formation<sup>128</sup>. It should be noted that weak peaks around 410 nm and 435 nm are present in both samples already at time zero (Fig. 9). This shows that some dityrosine cross-links have been generated even before the experiment was initiated, which is consistent with previous reports stating that  $\text{A}\beta$  peptides can induce oxidative stress on their own, especially in somewhat aggregated states<sup>129,130</sup>.

## Discussion

Nickel is a well-known neurotoxicant, but its role in neurodegenerative diseases remains unclear<sup>44</sup>. Several studies have investigated the possible effects of transition metals such as Cu and Zn in AD neuropathology, with an emphasis on interactions with the amyloid-forming  $\text{A}\beta$  peptides<sup>29–32</sup>. We therefore interpret our current results on  $\text{A}\beta$  interactions with Ni(II) ions mainly in the light of earlier work on  $\text{A}\beta$  binding to Cu(II) and Zn(II) ions.

**Residue-specific binding of Ni(II) ions to  $\text{A}\beta$  peptides.** Our NMR results show that equimolar amounts of Ni(II) ions display residue-specific binding to the N-terminal segment of the  $\text{A}\beta_{40}$  peptide (Fig. 1). This is in line with earlier studies showing that Ni(II) ions can bind N-terminal  $\text{A}\beta$  fragments<sup>45–47</sup>. The 2D  $^1\text{H}$ - $^{13}\text{C}$ -HSQC NMR data (Fig. 2) suggest that the three histidine residues His6, His13, and His14 are involved as binding ligands, possibly together with the Tyr10 residue. Previous work has established the metal-binding capacity of the Tyr phenol ring<sup>131</sup>, and in  $\text{A}\beta$  peptides the Tyr10 residue seems to be involved in binding to Pb(IV) ions<sup>38</sup>. The weaker Ni(II)/ $\text{A}\beta_{40}$  interactions observed at low pH (Fig. 1) further support the histidines being binding ligands, as these residues become protonated at low pH and therefore less prone to interact with cations<sup>92,106,132</sup>. The CD spectroscopy measurements also support the histidines being involved as binding ligands: addition of Ni(II) ions induces structural changes in  $\text{A}\beta_{40}$  peptides, but not in  $\text{A}\beta_{40}$ (NoHis) mutant peptides (Fig. 3). This indicates that Ni(II) ions do not bind  $\text{A}\beta$  peptides when the His residues are absent, which is not surprising, given that Ni(II) ions are known to bind His residues such as those in protein His-tags<sup>133</sup>. Thus, Ni(II) ions seem to belong to a family of metal ions that coordinate to the  $\text{A}\beta$  N-terminal segment mainly by the His residues, just like Ag(I), Cu(II), Fe(II), Hg(II), Mn(II), Zn(II), and possibly Pb(IV) ions<sup>30,37,38,40,47,52,53,92,134,135</sup>. The exact binding coordination could not be determined from our measurements, and it is possible that multiple alternating binding conformations exist, as has been shown for Cu(II) ions<sup>136</sup>.

According to the Irving-Williams series<sup>137</sup>, the binding affinities of certain divalent metal ions to peptides and proteins should follow the order  $\text{Mn(II)} < \text{Fe(II)} < \text{Co(II)} < \text{Ni(II)} < \text{Cu(II)} > \text{Zn(II)}$ . Metal binding affinities are however notoriously difficult to quantify, as they tend to vary both with the experimental conditions (buffer, temperature) and the employed measurement technique<sup>138</sup>. For example, binding affinities varying by several orders of magnitude have previously been reported for the  $\text{A}\beta$ -Cu(II) complex, with a consensus value in the low nM region for buffer-corrected affinity<sup>138</sup>. In our earlier studies, we have reported apparent (not buffer-corrected)  $K_D$  values around 50–100  $\mu\text{M}$  for Mn(II) ions in phosphate buffer, pH 7.35<sup>37</sup>, around 1–10  $\mu\text{M}$  for Zn(II) ions in phosphate or Hepes buffer, pH 7.2<sup>40</sup>, and around 0.5–2.5  $\mu\text{M}$  for Cu(II) ions in phosphate or Hepes buffer, pH 7.2–pH 7.35<sup>40,96,106</sup>.

Both the CD and the NMR measurements suggest an affinity in the low  $\mu\text{M}$  range for Ni(II) binding to  $\text{A}\beta$  peptides (Fig. 4), i.e. weaker than Cu(II) ions, stronger than Mn(II) ions, and perhaps somewhat similar to Zn(II) binding affinity, which would be consistent with the Irving-Williams series. As the Ni(II) ions bind to the N-terminal  $\text{A}\beta$  segment, the binding affinity should be rather the same for  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  peptides, and also for shorter  $\text{A}\beta$  versions such as  $\text{A}\beta(1–28)$  and  $\text{A}\beta(1–16)$ . The CD measurements indicate that the Ni(II) binding affinity to the truncated  $\text{A}\beta(4–40)$  peptide is similar to, or even somewhat weaker than, the affinity to the full-length  $\text{A}\beta_{40}$  peptide (Figs. 3 and 4). This is unexpected, as the  $\text{A}\beta(4–40)$  peptide has been reported to contain an N-terminal binding motif that supposedly provides very strong binding to Cu(II) and Ni(II) ions<sup>139</sup>, i.e. possibly fM affinity for Cu(II) ions<sup>140</sup>. Binding of metal ions to truncated  $\text{A}\beta$  variants is biologically relevant as such variants, and especially  $\text{A}\beta(4–42)$ , are abundant in amyloid plaques from both healthy and AD brain tissues<sup>141–144</sup>.

**Effects of Ni(II) ions on  $\text{A}\beta$  structure and aggregation.** Similar to e.g. Ag(I), Cu(II), Hg(II), and Zn(II) ions<sup>39,40,52,53</sup>, Ni(II) ions retard  $\text{A}\beta_{40}$  amyloid formation in a concentration-dependent manner by directing the aggregation pathways towards non-fibrillar amorphous aggregates as demonstrated both by ThT fluorescence and AFM imaging (Figs. 5 and 6). Already at a 1:1 Ni(II)/ $\text{A}\beta$  ratio,  $\text{A}\beta_{40}$  fibrillation appears to be com-

pletely inhibited. This supports earlier studies reporting that Ni(II) ions can influence protein aggregation<sup>145</sup>. We have previously shown that low Zn(II) concentrations induce a Zn(II)-bound structure that prevents the A $\beta$  peptides from forming the  $\beta$ -hairpin required for fibrillation<sup>19,40</sup>. At higher Zn(II) concentrations  $\beta$ -sheet structure was induced<sup>92</sup>, similar to our current observations with CD spectroscopy that Ni(II) ions induce  $\beta$ -sheet structure in A $\beta_{40}$  and A $\beta_{4-40}$  peptides (Fig. 3D,F). A $\beta$  aggregation is promoted by the direct electrostatic effect of binding cations to the anionic A $\beta$  peptides, thereby reducing repulsion between the A $\beta$  peptides<sup>40</sup>. Given that Ni(II) and Zn(II) ions have similar charge and binding ligands, they likely affect A $\beta$  aggregation and fibrillation via similar mechanisms.

Although A $\beta$  fibrils, such as those shown in Fig. 6A,B, are the end products of A $\beta$  aggregation, intermediate aggregates known as soluble oligomers are now generally considered to be the main toxic species in AD pathology<sup>146,147</sup>. The toxic mechanisms are unclear, but may involve membrane disruption<sup>30</sup>, as some studies have reported that A $\beta$  oligomers can form membrane-spanning “pores” that can induce leakage of e.g. Ca(II) ions<sup>148</sup>. Interestingly, other studies have reported that this harmful Ca(II) leakage can be inhibited by histidine-associating compounds, such as imidazole, Zn(II), and Ni(II) ions<sup>41,149</sup>. Because Cu(II), Zn(II), and other divalent ions have been shown to affect the structure, stability, and/or toxicity of A $\beta$  oligomers<sup>149–152</sup>, it is worth noting that both our FTIR (Figs. 8 and S2) and CD results (Figs. 3 and S1) show that Ni(II) ions induce structural changes in both A $\beta$  oligomers and A $\beta$  monomers. This is in line with earlier studies showing that both SDS-stabilized A $\beta_{22}$  oligomers<sup>81,153,154</sup>, and SDS micelle-bound A $\beta$  monomers<sup>51,96</sup> contain surface-exposed N-termini which makes it possible for the N-terminal H6, H13, and H14 residues to interact with metal ions. We speculate that Ni(II) ions affect A $\beta$  oligomer structure in similar ways as Cu(II) and Zn(II) ions do, even though the exact mechanisms are not fully understood<sup>30</sup>. Addition of Ni(II) ions reduces the intensity of the NMR crosspeaks for monomeric A $\beta_{40}$  peptides in random coil structure (Fig. 1), showing that this conformation becomes less populated. But no new NMR crosspeaks appear (Fig. 1), which shows that the Ni(II) ions do not bind to form a single well-defined Ni(II)-A $\beta$  complex. Instead, a range of heterogeneous  $\beta$ -sheet-containing structures are induced, which most likely exist in different stages of aggregation. They can be observed in CD and FTIR spectra, but not in NMR spectra<sup>92,94</sup>.

**Effects of Ni(II) ions on A $\beta$  dityrosine formation.** Ni(II) ions may affect the A $\beta$  aggregation processes also via formation of reactive oxygen species (ROS). Nickel is well known as a redox-active metal that can adopt a wide range of oxidation states, i.e., from  $-1$  to  $+4$ <sup>155</sup>. While this can be usefully employed in engineering contexts such as in Ni–Cd batteries, in biological systems it means that Ni can induce oxidative stress, and this may be one of the main mechanisms of Ni toxicity<sup>69</sup>. Our experiments show that addition of Ni(II) ions initiates formation of A $\beta_{40}$  dityrosine cross-links (Fig. 9), which is a common ROS effect. Earlier studies have shown that bound redox-active Cu ions can initiate dityrosine formation, both in A $\beta$  and other peptides and proteins<sup>96,122–125,152,156,157</sup>. It is therefore not surprising that a similar effect is observed for Ni(II) ions, especially as the NMR results indicate that Tyr10 is one of the Ni(II) binding ligands (Fig. 2). As wt A $\beta$  peptides only contain one Tyr residue, i.e. Tyr10, dityrosine formation must involve two A $\beta$  peptides, which then combine into a covalently linked dimer. Such dityrosine-linked A $\beta$  dimers are of biological significance, as they have been found in amyloid plaques in AD brains<sup>158</sup>. As these plaques contain elevated levels of bound redox-active Cu and Fe ions<sup>26,27</sup>, it is likely that the A $\beta$  dityrosine links observed in AD patients are generated by metal-induced ROS. Because dimerization is the first step towards peptide aggregation, dityrosine formation in A $\beta$  peptides is clearly a process that influences aggregation. In vitro studies have shown that dityrosine-linked A $\beta$  dimers undergo rapid aggregation into oligomers that are stable, soluble, and neurotoxic<sup>159</sup>.

## Conclusions

We here show for the first time that Ni(II) ions bind to the N-terminal segment of biologically relevant (i.e., full-length) A $\beta$  peptides. The Ni(II) binding affinity is in the low  $\mu$ M range, with the three N-terminal His residues and possibly Tyr10 involved as binding ligands. At equimolar amounts, Ni(II) ions impede A $\beta$  fibrillation by directing the aggregation towards amorphous aggregates. The redox-active Ni(II) ions induce dityrosine cross-links via redox chemistry, thereby creating covalent A $\beta$  dimers. Ni(II) ions induce structural alterations in A $\beta$  monomers, both in aqueous buffer (formation of  $\beta$  sheets) and in membrane-mimicking SDS micelles (likely formation of coil-coil helix), and affect also A $\beta$  oligomerization. Although Ni(II) binding to A $\beta$  is somewhat weaker than Cu(II) binding, the two metal ions induce similar effects on A $\beta$  structure and aggregation. Exposure to stoichiometric amounts of Ni(II) ions induces formation of heterogeneous A $\beta$  oligomers, which can be observed with CD and IR but not NMR spectroscopy. These oligomers, which are in a dynamic equilibrium with A $\beta$  monomers, may be important contributors to AD brain pathology.

## Data availability

All data generated or analysed during this study are included in this published article (and its supplementary information files). The raw data for the spectroscopy measurements are available from the corresponding author on reasonable request.

**ABSTRACT:** Copper is an indispensable biometal, primarily serving as a redox-competent cofactor in numerous proteins. Apart from preformed copper-binding sites within the protein structures, small peptide motifs exist called ATCUN, which are composed of an N-terminal tripeptide XZH, able to bind Cu(II) ions in exchangeable form. These motifs are common for serum albumin, but they are also present in a wide range of proteins and peptides. These proteins and peptides can be involved in copper metabolism, and copper ions can affect their biological role. The distribution of copper between the ATCUN peptides, including truncated amyloid- $\beta$  ( $A\beta$ ) peptides  $A\beta$ 4–42 and  $A\beta$ 11–42, which may be involved in Alzheimer's disease pathogenesis, is mainly determined by their concentrations and relative Cu(II)-binding affinities. The Cu(II)-binding affinity ( $\log K_d$ ) of several ATCUN peptides, determined by different methods and authors, varies by more than three orders of magnitude. This variation may be attributed to the chemical properties of peptides but can also be influenced by the differences in methods and experimental conditions used for the determination of  $K_d$ . In the current study, we performed direct competition experiments between selected ATCUN peptides and HSA by using an LC-ICP MS-based approach. We demonstrated that ATCUN and truncated  $A\beta$  peptides  $A\beta$ 4–16 and  $A\beta$ 11–15 bind Cu(II) ions with an affinity similar to that for HSA. Our results demonstrate that ATCUN motifs cannot compete with excess HSA for the binding of Cu(II) ions in the blood and cerebrospinal fluid.

## INTRODUCTION

Copper is an essential microelement for all forms of life, but its chemical properties make it potentially toxic, which is why its metabolism is always tightly regulated in living organisms. The biological functions of copper are almost exclusively carried out in the protein-bound form. Bioinformatic analysis revealed that Cu proteome constitutes approximately 0.05–1.3% of the total proteome of an organism, considering both eukaryotes and prokaryotes.<sup>1</sup> It is estimated that there are 54 Cu-binding proteins in the human proteome.<sup>2</sup>

In addition to 3D copper-binding pockets within protein structures, Cu(II) ions can also strongly bind to an N-terminal motif called ATCUN (amino terminal Cu- and Ni-binding motif). The ATCUN motif contains a His residue in the third position (XZH) and is present in more than 400 human proteins, including human serum albumin (HSA).<sup>3</sup> Approximately 10% of the total copper present in human serum is bound to the ATCUN motif of HSA. This copper binding is exchangeable, and it is possible that all other extracellular ATCUN proteins can also play a role in copper metabolism or that their biological functions may depend on copper binding.

To participate in copper metabolism or perform their biological functions, other extracellular ATCUN proteins must compete with HSA for copper binding. The amount of copper that these proteins can bind depends on their relative concentration and affinity for metal binding. The metal-binding affinities of peptides with an ATCUN motif have been intensively studied by different methods, and the range of  $\log K_d$  values determined for ATCUN sites ranges from 11.0 to 14.6.<sup>4</sup> Selected values of dissociation constants for ATCUN motif-containing peptides and proteins from the literature are listed in Table 1.

ATCUN complexes have a characteristic four-nitrogen (4N) square-planar coordination mode, where the metal ion is

located in the center of a square whose edges are occupied by four nitrogen atoms, provided by the N-terminal amine, two subsequent nitrogen atoms in peptide backbone, and the N-1 nitrogen of the His imidazole ring (Figure 1).

**Figure 1.** Schematic presentation of the Cu(II)–ATCUN complex.

Numerous explanations have been proposed to account for the differences in reported  $K_d$  values for ATCUN motifs, such as differences in the  $pK_a$  values of individual peptide nitrogens,<sup>12,13</sup> variances in the hydrophobicity of the first two amino acid residues,<sup>13</sup> and variances in the secondary coordination sphere effects. Although all of these factors may influence Cu(II)-binding affinities to some extent, differences might also be caused by using many different methods for calculating metal-binding affinities. It is well known that such measurements are strongly affected by the experimental conditions, which typically vary between different studies.<sup>14</sup> An example depicting this is the data showing that two residues at the N-terminal side of His3 do not significantly contribute to the binding of Cu(II) ions.<sup>12</sup> This uncertain situation complicates the possibility of studying copper trafficking in the organisms and modeling the availability of copper ions to different peptides and proteins.

The binding of Cu(II) to an ATCUN motif substantially alters the electrochemical properties of the Cu(II)/Cu(I) redox couple. The Cu–ATCUN complex has antioxidant properties, as it shows a redox-silent component in the presence of the biological reductant ascorbate due to its high redox potential and inherent geometry problem between Cu(II) and Cu(I) complexes.<sup>15</sup>

Having a clear understanding of copper trafficking is crucial for understanding the possible involvement of copper ions in Alzheimer's disease (AD) pathogenesis. AD is characterized by the initial formation of amyloid plaques in the brain, followed by formation of neurofibrillary tangles inside the neurons.<sup>16</sup> Amyloid plaques are composed of amyloid- $\beta$  peptides (A $\beta$ ) of various lengths, mainly A $\beta$ 1–40 and A $\beta$ 1–42.<sup>16,17</sup> However, an initial study by Masters et al. demonstrated that the plaques contained a significant amount of the truncated A $\beta$ 4–42

peptide.<sup>18</sup> In later mass spectrometric studies, substantial amounts of truncated A $\beta$ 4–42<sup>19</sup> and A $\beta$ 11–42 peptides<sup>20,21</sup> were found in plaques as well as in the cerebrospinal fluid (CSF).<sup>22</sup> Since both truncated peptides carry the ATCUN motifs, it raises the question of whether A $\beta$  peptides can bind Cu(II) ions in vivo in the presence of HSA.

The interactions of A $\beta$  peptides with Cu(II) ions have been extensively studied. It has been demonstrated that full-length A $\beta$  peptides can bind Cu(II) ions with relatively strong affinity, with a  $K_d$  value up to 0.1–1 nM,<sup>14,23,24</sup> which is still several orders of magnitude lower than that of HSA. Truncated A $\beta$  peptides A $\beta$ 4–X and A $\beta$ 11–X contain the FRH- and EVH-ATCUN motifs, respectively. By using potentiometric titration, it was demonstrated that A $\beta$ 4–16 binds Cu(II) with a conditional  $K_d$  value of  $3 \times 10^{-14}$  M at pH 7.4,<sup>4</sup> which characterized at that time 30 times higher affinity than that for HSA ( $K_d = 1 \times 10^{-12}$  M was determined from the competition with NTA<sup>25</sup>). Based on these results, it was suggested that A $\beta$ 4–40 could have a physiological role in copper homeostasis,<sup>4</sup> which might be linked to the scavenging of Cu(II) ions in the synaptic cleft.<sup>26</sup> The Cu(II)-binding affinity of A $\beta$ 11–40 determined from the results of CD spectroscopic titration of the Cu(II)–A $\beta$ 11–40 complex with His and Gly is similar to that for A $\beta$ 4–16, i.e.,  $K_d = 3.4 \times 10^{-14}$  M.<sup>11</sup> At that time, this pointed toward efficient competition with HSA. Recently, the  $K_d$  value for HSA was corrected to  $0.955 \times 10^{-13}$  M by using potentiometric titration,<sup>7</sup> which reflects only three times lower affinity than those for A $\beta$ 4–16 and A $\beta$ 11–40. HSA is present in CSF at 3  $\mu$ M concentration,<sup>27</sup> which is much higher than the nM concentration of A $\beta$  peptides.<sup>28</sup> These data suggest that A $\beta$  peptides should not be able to compete with HSA for Cu(II) binding.<sup>11</sup> However, direct competition experiments have not yet been conducted.

In this study, we attempted to answer the following two related questions: “Do different ATCUN motifs show different Cu(II)-binding affinities under the conditions of direct competition?” “Can truncated A $\beta$  peptides with ATCUN motifs compete in CSF with HSA for the binding of Cu(II) ions?” To address the raised questions, we employed an innovative LC-ICP MS technique, enabling the use of size exclusion chromatography (SEC) to separate and quantify the substances with high molecular weight (HSA) and low molecular weight (ATCUN peptides) involved in metal binding within the reaction mixture.<sup>29</sup>

We determined the relative Cu(II)-binding affinities for several model peptides and two truncated A $\beta$  peptides in comparison with HSA. Results demonstrate that different ATCUN-containing peptides and HSA have very similar Cu(II)-binding affinities, and truncated A $\beta$  peptides cannot

compete with HSA for the binding of Cu(II) ions in blood or even in CSF.

## RESULTS

First, Cu(II) competition experiments were performed with the aim of determining the incubation time required to achieve the equilibrium of Cu(II) distribution between HSA- and ATCUN-containing peptides. Figure 2 demonstrates that equilibrium is reached within 30 min.

Kinetic experiments were also conducted in conditions where A $\beta$ (11–15) was added to the metalated HSA (Figures S1 and S2) and when HSA was added to the metalated A $\beta$ (11–15) (data not shown). In the first case, equilibrium was reached in 30 min (Figure S3) both in the equimolar mixture and in the presence of a 2-fold excess of the competing (apo) ligand. In the second case, the equilibrium was reached very quickly within 2 min. Based on this kinetic information for subsequent experiments, Cu(II) ions were added to the mixture of HSA and ATCUN peptides, and an incubation time of 30 min was selected.

The next series of experiments involved determining the competition between HSA and ATCUN peptides for Cu(II) binding. Figure 3 shows an example of the results obtained with the A $\beta$ (11–15) peptide. When this peptide and HSA are present in equimolar concentrations, Cu(II) ions are distributed 60% in HSA and 40% in the A $\beta$ (11–15) peptide (Figure 3c). This suggests that both HSA and the A $\beta$ (11–15) peptide are able to compete almost equally for Cu(II) binding. As the A $\beta$ (11–15) concentration is increased, the distribution of Cu(II) ions shifts toward the peptide, and at an A $\beta$ (11–15) concentration of 40  $\mu$ M, the metal distribution reaches a ratio of 13:87 in favor of the A $\beta$ (11–15) peptide (Figure 3g).

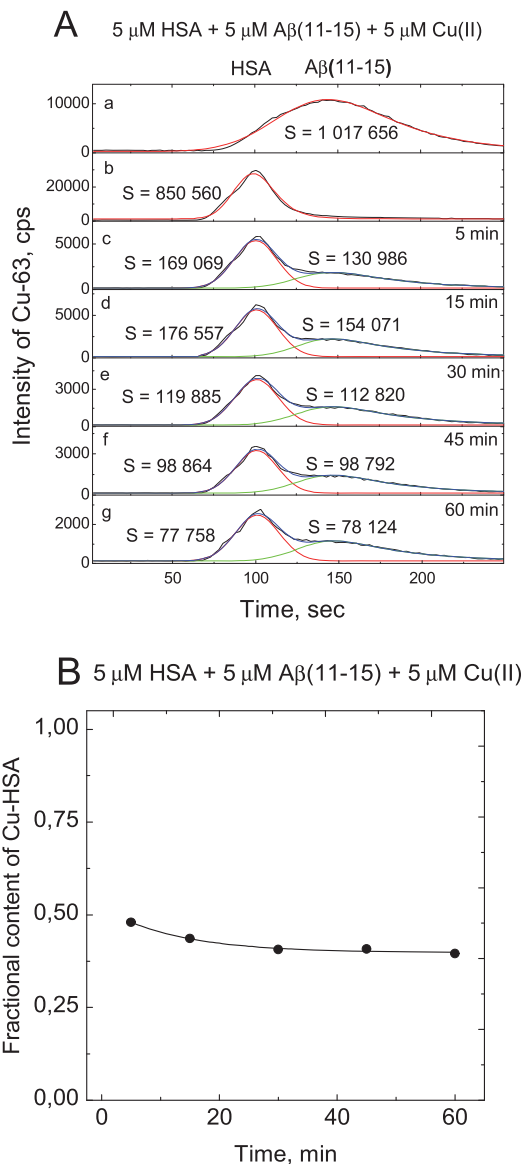

The obtained results were analyzed according to eq 2, which predicts a linear relationship between  $X = [\text{Cu}(\text{Pept})]/([\text{HSA}]_T - [\text{Cu}(\text{HSA})])$  and  $Y = [\text{Cu}(\text{HSA})]/([\text{Pept}]_T - [\text{Cu}(\text{Pept})])$ , where  $[\text{Cu}(\text{HSA})]$  and  $[\text{Cu}(\text{Pept})]$  are determined from the chromatograms as the copper content of high- and low-molecular-weight fractions and  $[\text{HSA}]_T$  and  $[\text{Pept}]_T$  are the total added concentrations of each ligand (see eqs 1–4 from the Materials and Methods). The relationship observed from three independent experiments is shown in Figure 4B, and it is linear with a slope of  $K_d(\text{A}\beta 11-15)/K_d(\text{HSA})$  equal to  $1.56 \pm 0.09$ . Using the known value of  $K_d$  for HSA, which is equal to  $0.955 \times 10^{-13}$  M,<sup>7</sup> we can calculate the  $K_d$  value for A $\beta$ 11–15 to be  $1.49 \pm 0.09 \times 10^{-13}$  M.

The representative examples of primary data for other ATCUN peptides are provided in the Supporting Information. Relationships between X and Y, based on eq 2, for these peptides are shown in Figures 5 and S8.

The obtained  $K_d$  values are presented in Table 2.

## DISCUSSION

The distribution of copper ions between competing ligands, such as peptides and proteins with ATCUN motifs, is determined by thermodynamic and kinetic factors. The distribution in equilibrium can be calculated from the  $K_d$  values of the ATCUN–Cu(II) complexes. However, the  $K_d$  values can be affected by several factors; for instance, they can be affected by experimental conditions and intermolecular interactions at higher concentrations of the reagents. In this paper, we have determined the relative binding affinities for different Cu(II)-binding ligands in direct competition experi-

**Figure 2.** Competition between HSA and A $\beta$ (11–15) peptide for Cu(II) ions. (A) SEC chromatograms of copper distribution (incubation time and integrated peak area values are shown in labels). (B) Decrease of the relative content of copper in the HSA fraction with time. Conditions: 5  $\mu$ M HSA, 5  $\mu$ M A $\beta$ (11–15), and 5  $\mu$ M Cu(II); incubation buffer 50 mM HEPES, 50 mM NaCl, pH 7.4; LC-ICP MS: column, 1 mL Sephadex G25 Superfine; elution buffer 200 mM  $\text{NH}_4\text{NO}_3$ , pH 7.4; flow rate 0.4 mL/min; injection volume 10  $\mu$ L; Cu-63 was monitored by ICP MS.

ments with binary mixtures. We have conducted such experiments with different Cu(II)-binding peptides and HSA as standard by using LC-ICP MS technology, which is suitable for this purpose. In these experiments, the different ATCUN-containing peptides display rather similar abilities to compete

**Figure 3.** Competition between HSA and the  $A\beta(11-15)$  peptide for  $Cu(II)$  ions. SEC chromatograms of (a)  $5 \mu M Cu(II) \bullet A\beta(11-15)$ , (b)  $5 \mu M Cu(II) \bullet HSA$ , and (c–g)  $5 \mu M HSA$  and  $Cu(II)$  in the presence of increasing concentration of  $A\beta(11-15)$ . The peptide concentrations and peak areas are shown in labels. Conditions; incubation buffer 50 mM HEPES, 50 mM NaCl, pH 7.4; incubation time 30 min; LC-ICP MS: column, 1 mL Sephadex G25 Superfine; elution buffer 200 mM  $NH_4NO_3$ , pH 7.4; flow rate 0.4 mL/min; injection volume 10  $\mu L$ ; Cu-63 was monitored by ICP MS.

with HSA for  $Cu(II)$  ions. Correspondingly, their binding affinities toward  $Cu(II)$  ions are also similar. These results are different from the results of potentiometric titration measurements. A comparison between  $DAH-NH_2$  and  $DAH-COOH$  indicates that C-terminal amidated peptides have slightly higher binding affinities than peptides with a free C-terminal carboxyl group, which is in agreement with the literature.<sup>8</sup> At the same time, the  $K_d$  value for  $DAH-NH_2$ , a tripeptide originating from HSA, was almost similar to the  $K_d$  value for HSA, demonstrating that amidated tripeptides can be good and sufficient  $Cu(II)$ -binding models for ATCUN-containing proteins.

In the literature, the amidated hexa- and heptapeptides (DTHFPI- $NH_2$  and MEHFPGP) have shown binding affinities that exceed that of HSA by 44 and 73 times, respectively (Table 1). However, in the direct competition experiments, these peptides displayed rather similar  $K_d$  values to HSA and also to the simplest model peptide GGH. This result suggests that the primary coordination sphere of the ATCUN motif, composed of four nitrogen atoms provided by the N-terminal amine, two subsequent peptide nitrogen atoms, and the N-1 nitrogen of the His imidazole ring, plays a crucial role in the binding of  $Cu(II)$  ions and determines the binding affinity. It also suggests that the chemical properties of the first two amino acid side chains and the post-His amino acid residues do not contribute significantly to the metal binding.

**Figure 4.** Calculation of the relative  $Cu(II)$ -binding affinity of  $A\beta(11-15)$  from LC-ICP MS results. (A) Decrease of the fractional content of the  $Cu \bullet HSA$  complex, caused by the increase of  $A\beta(11-15)$  concentration. (B) Application of eq 2. Results of three separate experiments are presented with different colors—red, blue, and black.

Direct competition experiments showed that truncated  $A\beta$  peptides, i.e.,  $A\beta 4-16$  and  $A\beta 11-15$ , have  $K_d$  values similar to HSA for  $Cu(II)$  binding (Table 2).  $A\beta 11-15$  has a 1.3 times higher affinity toward  $Cu(II)$  ions than  $A\beta 4-16$ . This small difference might be explained by the His14 residue contributing to ATCUN motif  $Cu(II)$  binding in the  $A\beta 11-15$  peptide. HSA is present in blood at  $650 \mu M$ <sup>30</sup> and in CSF at  $3 \mu M$  concentration,<sup>27</sup> which are much higher than the nM concentrations of  $A\beta$  peptides in CSF and blood.<sup>28,31</sup> Based on these numbers, we conclude that  $A\beta$  peptides cannot compete with HSA for  $Cu(II)$  binding<sup>11</sup> in blood or CSF.

Overall, we argue that the direct competition experiments with HSA and the  $K_d$  values determined from these experiments describe the properties of ATCUN-motif-containing peptides in biological conditions more correctly than the  $K_d$  values determined from separate potentiometric titration experiments. In the latter case, the interactions between the peptides in the solution may also affect the titration results in a way that does not occur in biological conditions where the peptide concentration is very low.

## CONCLUSIONS

Peptides with His in the third position are known as ATCUN peptides, which are able to bind  $Cu(II)$  ions with a high affinity. In the literature, the reported dissociation constants for different ATCUN peptides vary widely. We performed direct competition experiments with selected ATCUN motifs, including truncated  $A\beta$  peptides, in relation to HSA using an LC-ICP MS-based approach. We demonstrated that  $Cu(II)$ -

**Figure 5.** Calculation of the relative Cu(II)-binding affinity of ATCUN peptides from LC-ICP MS results according to eq 2. (A) DAH-COOH, (B) DAH-NH<sub>2</sub>, (C) MDH-NH<sub>2</sub>, (D) GGH-NH<sub>2</sub>, (E) DTHFPI-NH<sub>2</sub>, and (F) MEHFPGP-NH<sub>2</sub>. Results of three separate experiments are presented with different colors: red, blue, and black.

binding affinities of ATCUN and truncated A $\beta$  peptides are similar to those for HSA and vary in a narrow range. Our results demonstrate that ATCUN motifs cannot remove substantial amounts of Cu(II) ions from excess HSA in blood and CSF environments.

## MATERIALS AND METHODS

**Materials.** The following lyophilized protein and peptides were used: human serum albumin (HSA) from Sigma/Merck (Darmstadt, Germany), A $\beta$ (4–16) and A $\beta$ (11–15) peptides from rPeptide (Watkinsville, GA), and DAH-COOH, DAH-NH<sub>2</sub>, MDH-NH<sub>2</sub>, GGH-NH<sub>2</sub>, DTHFPI-NH<sub>2</sub>, and MEHFPGP-NH<sub>2</sub> were synthesized at the Institute of Technology of the University of Tartu. The peptides were

synthesized on an automated peptide synthesizer (Biotage Initiator+ Alstra, Sweden) using a fluorenylmethyloxycarbonyl (Fmoc) solid-phase peptide synthesis strategy and purified by reverse-phase liquid chromatography on a C4 column (Phenomenex Jupiter C4, 5  $\mu$ m, 300 Å, 250  $\times$  10 mm) using a gradient of acetonitrile/water containing 0.1% TFA. The molecular weight of the peptides was determined by a MALDI-TOF mass spectrometer (Bruker Microflex LT/SH). 1,1,1,3,3,3-Hexafluoro-2-propanol (HFIP), sodium chloride, sodium hydroxide, and 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (Hepes) were purchased from Sigma-Aldrich (St. Louis, MO). Cu(II)acetate was purchased from Sigma (Sigma/Merck KGaA, Darmstadt, Germany). Nitric acid (HNO<sub>3</sub>, trace metal grade) was purchased from Fisher

Scientific (UK Limited Leicestershire, UK), and ammonium hydroxide 25% solution was from Honeywell Fluka (Seelze, Germany). Ultrapure Milli-Q water with a resistivity of 18.2 M $\Omega$ /cm, produced by a Merck Millipore Direct-Q & Direct-Q UV water purification system (Merck KGaA, Darmstadt, Germany), was used for all applications.

**Competition for Cu(II) Ions Determined by LC-ICP MS Analysis. Sample Preparation.** All lyophilized peptides were dissolved in HFIP at a concentration of 100  $\mu$ M to disassemble the preformed aggregates. The solution was divided into aliquots; HFIP was evaporated in vacuum, and the tubes containing the peptide film were stored at  $-80$  °C until used.

A stock solution of HSA was prepared in Milli-Q water and further diluted into a reaction buffer solution composed of 50 mM HEPES and 50 mM NaCl, pH 7.4. HFIP-treated peptide aliquots were dissolved in 50 mM HEPES and 50 mM NaCl, pH 7.4, at a concentration of 50  $\mu$ M and further diluted to the final concentration with reaction buffer. Cu(II)acetate was used as a Cu(II) source for proteins and peptides. For a competition experiment, an appropriate concentration of competing peptides (A $\beta$ (11–15), A $\beta$ (4–16), DAH-COOH, DAH-NH<sub>2</sub>, MDH-NH<sub>2</sub>, GGH-NH<sub>2</sub>, DTHFPI-NH<sub>2</sub>, or MEHFPGP-NH<sub>2</sub>) and a 5  $\mu$ M solution of HSA were mixed with 5  $\mu$ M Cu(II), and the sample was incubated 30 min at room temperature. All reagent solutions were prepared daily before experiments.

**LC-ICP MS Measurements.** For LC-ICP MS analyses, an Agilent Technologies (Santa Clara) Infinity HPLC system, which consisted of a 1260 series  $\mu$ -degasser, a 1200 series capillary pump, a Micro WPS autosampler, and a 1200 series MWD VL detector, was connected to an Agilent 7800 series ICP MS instrument. For instrument control and data acquisition, ICP MS MassHunter 4.4 software, version C 01.04, from Agilent was used. ICP MS was operated under the following conditions: RF power: 1550 W, nebulizer gas flow: 1.03 L/min, auxiliary gas flow: 0.90 L/min, plasma gas flow: 15 L/min, nebulizer type: MicroMist, and isotope monitored: Cu-63. To perform the separation of HMW and LMW pools, a 1 mL gel filtration column, self-packed with HiTrap Desalting resin Sephadex G25 Superfine (Amersham/GE Healthcare, Buckinghamshire, UK), was used. An injection volume of 10  $\mu$ L for each sample was used. The mobile phase for gel filtration was 200 mM NH<sub>4</sub>NO<sub>3</sub> at pH 7.5, prepared from TraceMetal grade nitric acid and ammonium hydroxide 25% solution, which is compatible with ICP MS. An ICP MS compatible flow rate of 0.4 mL/min was used in all separations. To get rid of contaminating metal ions in the buffer, the mobile phase was eluted through the Chelex 100 Chelating Ion

Exchange resin (Sigma, Merck KGaA, Darmstadt, Germany) prior to liquid chromatographic separation. The demetalation of the SEC columns before each experiment was conducted by injecting 1 mM EDTA into the columns (injection volumes were the same for all experiments).

Separation of the HMW and LMW peak areas was conducted with Origin Pro 8.5 software. An exponentially modified Gaussian peak function (GaussMod) was used to obtain peak areas that were further used to calculate a decrease in the fractional content of the metalated protein. All experiments were repeated three times.

**Determination of Relative Dissociation Constants.** Experimental results for competition for Cu(II) ions between HSA- and ATCUN-containing peptides were used for the determination of the relative dissociation constant for the ATCUN-containing peptide and HSA copper complexes. The ratio of the dissociation constants for the peptide and HSA can be expressed as follows<sup>7</sup>

$$\frac{K_{d(\text{Pept})}^{\text{Cu}}}{K_{d(\text{HSA})}^{\text{Cu}}} = \frac{[\text{Cu}(\text{HSA})][\text{Pept}]_{\text{T}} - [\text{Cu}(\text{Pept})]}{[\text{Cu}(\text{Pept})][\text{HSA}]_{\text{T}} - [\text{Cu}(\text{HSA})]} \quad (1)$$

or

$$\begin{aligned} &[\text{Cu}(\text{HSA})][\text{Pept}]_{\text{T}} - [\text{Cu}(\text{Pept})] \\ &= \frac{K_{d(\text{Peptide})}^{\text{Cu}}}{K_{d(\text{HSA})}^{\text{Cu}}} [\text{Cu}(\text{Pept})][\text{HSA}]_{\text{T}} - [\text{Cu}(\text{HSA})] \end{aligned} \quad (2)$$

$$X = [\text{Cu}(\text{Pept})][\text{HSA}]_{\text{T}} - [\text{Cu}(\text{HSA})] \quad (3)$$

$$Y = [\text{Cu}(\text{HSA})][\text{Pept}]_{\text{T}} - [\text{Cu}(\text{Pept})] \quad (4)$$

where [Cu(HSA)] and [Cu(Pept)] are determined from the chromatograms as the copper content of high- and low-molecular-weight fractions, and [HSA]<sub>T</sub> and [Pept]<sub>T</sub> are the total added concentrations of each ligand.

**ABSTRACT:** Uranium (U) is naturally present in ambient air, water, and soil, and depleted uranium (DU) is released into the environment via industrial and military activities. While the radiological damage from U is rather well understood, less is known about the chemical damage mechanisms, which dominate in DU. Heavy metal exposure is associated with numerous health conditions, including Alzheimer's disease (AD), the most prevalent age-related cause of dementia. The pathological hallmark of AD is the deposition of amyloid plaques, consisting mainly of amyloid- $\beta$  ( $\text{A}\beta$ ) peptides aggregated into amyloid fibrils in the brain. However, the toxic species in AD are likely oligomeric  $\text{A}\beta$  aggregates. Exposure to heavy metals such as Cd, Hg, Mn, and Pb is known to increase  $\text{A}\beta$  production, and these metals bind to  $\text{A}\beta$  peptides and modulate their aggregation. The possible effects of U in AD pathology have been sparsely studied. Here, we use biophysical techniques to study in vitro interactions between  $\text{A}\beta$  peptides and uranyl ions,  $\text{UO}_2^{2+}$ , of DU. We show for the first time that uranyl ions bind to  $\text{A}\beta$  peptides with affinities in the micromolar range, induce structural changes in  $\text{A}\beta$  monomers and oligomers, and inhibit  $\text{A}\beta$  fibrillization. This suggests a possible link between AD and U exposure, which could be further explored by cell, animal, and epidemiological studies. General toxic mechanisms of uranyl ions could be modulation of protein folding, misfolding, and aggregation.

**KEYWORDS:** Alzheimer's disease, amyloid aggregation, metal–protein binding, neurodegeneration, heavy metal toxicity

## 1. INTRODUCTION

Alzheimer's disease (AD) is the most common neurodegenerative disease among elderly people.<sup>1,2</sup> The main AD risk factors are old age and genetic factors such as unfavorable alleles of the ApoE gene and sometimes Down's syndrome<sup>1,2</sup> and also environmental risk factors such as smoking, diabetes, and traumatic brain injury.<sup>2–4</sup> Identifying molecular targets to diagnose and treat the disease is imperative,<sup>5,6</sup> and a number of drug candidates have been proposed with varying success.<sup>7–10</sup>

The main molecular events underlying AD pathology appear to be the aggregation of intrinsically disordered amyloid- $\beta$  ( $\text{A}\beta$ ) peptides and tau proteins into toxic soluble oligomers<sup>11–13</sup> and then into insoluble amyloid fibrils or tangles<sup>14</sup> that deposit as plaques in the brains of AD patients.<sup>2,15</sup> The  $\text{A}\beta$  peptides are cleaved by  $\beta$ - and  $\gamma$ -secretase enzymes from the  $\text{A}\beta$  precursor protein (APP) into peptides of different lengths,<sup>16</sup> where  $\text{A}\beta$  (1–40), i.e.,  $\text{A}\beta_{40}$ , and  $\text{A}\beta$  (1–42), i.e.,  $\text{A}\beta_{42}$ , are the most common.<sup>17</sup> Both variants are unstructured monomers in an aqueous solution but can adopt  $\beta$ -sheet<sup>18</sup> or  $\alpha$ -helix<sup>19</sup> secondary structures in other environments.<sup>20</sup> The  $\beta$ -sheet structure is of particular interest as  $\text{A}\beta$

peptides in  $\beta$ -sheet hairpin conformations appear to be the building blocks of the aggregated fibrils.<sup>18</sup>

The accumulation and aggregation of  $\text{A}\beta$  peptides can be influenced by a number of interacting factors,<sup>3,21</sup> such as other proteins and peptides,<sup>10,22,23</sup> including other amyloid peptides/proteins,<sup>24–27</sup> cationic molecules and metal ions,<sup>28–30</sup> and various small molecules.<sup>8</sup> Redox-active metal ions such as Cu(II) and Fe(II) are of special interest<sup>29,31,32</sup> as they are present in the plaques of AD brains.<sup>33,34</sup> For example, they can generate harmful oxygen radicals (reactive oxygen species, ROS) that may contribute to the AD pathology.<sup>35–38</sup> Heavy metals are generally known to be toxic, but their toxic mechanisms are not fully understood.<sup>39</sup> Known molecular mechanisms for metal toxicity include molecular and ionic

Published: July 24, 2023

mimicry,<sup>40</sup> but other mechanisms are also possible, such as modulation of protein misfolding or aggregation.<sup>41–43</sup> Thus, lead (Pb) ions not only compete with ions of essential metals such as zinc and calcium,<sup>44</sup> but they also increase the expression of APP and  $\beta$ -secretase,<sup>45</sup> and Pb(IV) ions bind to A $\beta$  peptides and modulate their aggregation.<sup>3</sup> Similar effects on A $\beta$  production and aggregation have been observed for the heavy metals mercury and cadmium.<sup>3,31,45–48</sup>

Uranium (U) is a heavy metal with known neurotoxic effects,<sup>39</sup> but these effects are sparsely studied, and a relation between U exposure and AD has not been established.<sup>49</sup> However, the blood–brain barrier does not prevent the transfer of U into the central nervous system (CNS),<sup>50</sup> and U has been shown to accumulate in the brain.<sup>51</sup> Uranium has no biological function in the human body,<sup>52,53</sup> and the adverse health effects of U exposure involve combined chemical and radiological mechanisms.<sup>54,55</sup> Although the chemical toxicity is more severe,<sup>56</sup> the radiological damage mechanisms are currently better understood.<sup>39,55</sup> The chemical toxicity obviously dominates in depleted uranium (DU), where the amount of the <sup>235</sup>U isotope has been significantly reduced in favor of the less radioactive (i.e., longer half-life) <sup>238</sup>U isotope.<sup>52</sup> As DU is used in military equipment, including certain ammunitions,<sup>57</sup> DU contamination has emerged as a potential environmental problem in regions of war such as Iraq and the Balkans,<sup>58–64</sup> with unclear health consequences for soldiers and civilians.<sup>52,54,65–67</sup> To what extent DU contributes to leukemia or lung cancer remains debated.<sup>68–71</sup>

Here, we use biophysical spectroscopic and imaging techniques to investigate the binding interactions between uranyl ions and the three A $\beta$  peptide variants A $\beta$ <sub>40</sub>, A $\beta$ <sub>42</sub>, and A $\beta$ <sub>40</sub> (H6A, H13A, and H14A) mutant. Of particular interest is the effect of uranyl on the A $\beta$  structure and aggregation.

**1.1. Chemical, Environmental, and Toxicological Aspects of Uranium and Uranyl Ions.** Uranium is present in ambient air, water, and soil. The highest human exposures result from drinking well water in geological regions rich in U.<sup>39,53,72–75</sup> Regulatory agencies have limited the highest allowed concentration of U in drinking water to 30  $\mu\text{g/L}$ ,<sup>76</sup> replacing a previous WHO limit of 15  $\mu\text{g/L}$ . Absorption of U is low regardless of exposure route and highly dependent on its solubility.<sup>39</sup> Inhaled U-dust particles of low solubility can be retained in tissues for many years.<sup>77</sup> Occupational exposure to U has historically involved workers in the production of phosphate fertilizers, workers producing glazed pottery, and miners handling uranium oxide, so-called “yellowcake”.<sup>39,78</sup> Sleep disturbances and possibly encephalitis have been linked to U exposure in former U mining districts in Kazakhstan.<sup>79</sup>

The main target for U toxicity is the kidney where atrophy and necrosis of glomerular walls have been noted.<sup>39,80–82</sup> Uranium also accumulates in bone.<sup>39,60,83–85</sup> Uranium crosses the blood–brain barrier to accumulate in the CNS.<sup>50</sup> Here, inhalation and ingestion of U yields heterogeneous but specific accumulations, most prominent in the hippocampus region,<sup>86</sup> responsible for memory recall. Rats surgically implanted with U pellets for 6 months have shown the presence of U in the cortex, midbrain, and cerebellum.<sup>87</sup> A study on mice showed toxic effects of DU in the mouse fetus,<sup>88</sup> indicating that U can also cross the placental barrier.

There are currently no known correlations between uranium exposure and diseases such as leukemia,<sup>73</sup> stomach cancer,<sup>89</sup> liver or bladder cancer,<sup>90</sup> or, as mentioned above, AD.<sup>49</sup> One study, however, found cerebrospinal fluid U concentrations,

albeit at low overall concentrations, to be significantly elevated in 17 patients with amyotrophic lateral sclerosis (ALS) when compared to 10 controls.<sup>91</sup> Studies in rodents have related U exposure to distorted social behavior<sup>92</sup> and weakened sensorimotor behavior.<sup>93</sup> Laboratory experiments using organisms such as rats and *Caenorhabditis elegans* have concluded with a low acute neurotoxic potential of U following exposure and a protective potential from the small metal-regulating protein metallothionein.<sup>87,94</sup> Protective effects have also been observed for the ghrelin hormone<sup>95</sup> and for antioxidant agents, including glutathione.<sup>96,97</sup>

The most predominant, most stable, and most relevant form of uranium in aerobic environments is the uranyl oxyanion,  $\text{UO}_2^{2+}$ . This ion is common in uranium-containing minerals, but it is also water-soluble and is present in the ocean at a concentration of 13.7 nM.<sup>98</sup> The uranyl ion is paramagnetic,<sup>99,100</sup> and in aqueous solution, it acts as a weak acid with a  $\text{pK}_a$  of around 4.2.<sup>101</sup> It behaves as a hard acceptor and prefers to form complexes with fluoride and oxygen donor atoms, preferably in planar geometry involving four, five, or even six binding ligands.<sup>102</sup> The capacity to accommodate five or six equatorial ligands in pentagonal or hexagonal bipyramidal coordination separates the uranyl ion from most other metal ions.<sup>98</sup> Thus, these uncommon binding geometries have been employed in attempts to design uranyl-specific binding proteins, e.g., to extract uranium from seawater.<sup>98</sup> As the most common form of uranium, most experimental studies of uranium toxicity have actually been conducted with uranyl ions rather than with metallic uranium, which is extremely rare in nature.

Interestingly, U intoxication and AD appear to have a common risk factor in the gene coding for apolipoprotein E (ApoE). U exposure in mice was found to induce cognitive impairment in ApoE-deficient (ApoE $^{-/-}$ ) males, together with some changes in cholesterol levels and metabolism.<sup>103,104</sup> This is consistent with the ApoE4 allele of the ApoE gene being a risk factor for mercury toxicity<sup>105,106</sup> and with ApoE-deficient mice showing increased iron accumulation in tissue over time.<sup>107</sup> It therefore appears likely that the ApoE protein is involved in regulating metal homeostasis. The ApoE4 allele is further linked to an increased probability of developing AD.<sup>108–112</sup> Why the ApoE gene is a risk factor for both heavy metal toxicity and AD is currently unclear, and various explanations have been proposed.<sup>108,113,114</sup> The previously suggested hypothesis that ApoE might bind and transport metal ions via Cys residues,<sup>105,106</sup> which are present in ApoE2 and ApoE3 but not in ApoE4, has recently been called into question.<sup>115</sup>

## 2. RESULTS

**2.1. ThT Fluorescence Measurements of A $\beta$ <sub>40</sub> Aggregation Kinetics.** The fluorescence intensity of ThT, a common marker for amyloid material,<sup>116</sup> was monitored when samples of 20  $\mu\text{M}$  A $\beta$ <sub>40</sub> peptides in 20 mM MES buffer, pH 7.3, were incubated with shaking for 15 h at 37 °C, together with different concentrations (0; 0.04; 0.2; 0.4; 2; and 20  $\mu\text{M}$ ) of uranyl acetate (Figure 1).

Fitting eq 1 to the ThT fluorescence curves in Figure 1 produced the kinetic parameters  $T_{\text{lag}}$  and  $t_{1/2}$  (Table 1). For the three highest concentrations of uranyl acetate, i.e., 0.4, 2, and 20  $\mu\text{M}$ , the ThT kinetic curves are mostly flat, and fitting eq 1 to these curves was not possible. The flat shape of the three curves indicates that no or very little amyloid material has

**Figure 1.** Monitoring the fibril formation of  $A\beta_{40}$  peptides via thioflavin T fluorescence.  $20 \mu\text{M}$   $A\beta_{40}$  was incubated at  $37^\circ\text{C}$  in  $20 \text{ mM}$  MES buffer, pH 7.3, together with different concentrations of uranyl acetate:  $0 \mu\text{M}$  (black);  $0.04 \mu\text{M}$  (gray);  $0.2 \mu\text{M}$  (green);  $0.4 \mu\text{M}$  (blue);  $2 \mu\text{M}$  (red); and  $20 \mu\text{M}$  (orange).

formed, although for the  $0.4 \mu\text{M}$  uranyl sample, small amounts of the ThT-binding material have begun to form after approximately 9 h. It is obvious that the amount of the amyloid material formed at the end of the measurements, i.e.,  $\Delta\text{ThT}$ , strictly decreases with the amount of added uranyl acetate (Figure 1 and Table 1). The two samples with 0 and  $0.04 \mu\text{M}$  uranyl both have aggregation half-times of around 3 h and lag times of around 2 h under the experimental conditions (Table 1). The aggregation of the  $0.2 \mu\text{M}$  uranyl sample is clearly slower, with a half-time of almost 7 h and a lag time of around 5 h. Given the visually estimated lag time of around 9 h for the  $0.4 \mu\text{M}$  uranyl sample and that the 2 and  $20 \mu\text{M}$  uranyl samples show no obvious signs of aggregation after 15 h, uranyl ions clearly increase the lag time for  $A\beta_{40}$  aggregation.

## 2.2. TEM Imaging of Aggregated $A\beta_{40}$ Peptides.

Negative staining transmission electron microscopy (TEM) images were recorded for  $20 \mu\text{M}$   $A\beta_{40}$  peptide, incubated for 20 h with different concentrations of uranyl acetate, i.e., 0, 0.2, 2, and  $20 \mu\text{M}$  (Figure 2). The uranyl additions correspond to uranyl/ $A\beta_{40}$  ratios of 1:100, 1:10, and 1:1. The control sample without  $\text{UO}_2^{2+}$  ions displays numerous amyloid fibrils that are several microns long, together with occasional larger clumps and smaller aggregates, which may be proto-fibrils (Figure 2A). This is in line with previous *in vitro* studies of  $A\beta_{40}$  aggregates.<sup>8,25,116</sup> The  $A\beta_{40}$  samples incubated together with  $0.2 \mu\text{M}$  of uranyl acetate display amyloid fibrils of similar size and shape (Figure 2B). In the presence of  $2 \mu\text{M}$  uranyl acetate, there are fewer fibrils and they are shorter, i.e., only a few microns long (Figure 2C). At the highest concentration of uranyl acetate, i.e.,  $20 \mu\text{M}$ , no fibrils have formed at all (Figure 2D). Instead, the  $A\beta_{40}$  peptides have aggregated into large amorphous clumps, which coexist with smaller particles

**Figure 2.** TEM images for aggregates of  $20 \mu\text{M}$   $A\beta_{40}$  in  $20 \text{ mM}$  MES buffer, pH 7.3, incubated for 20 h on a thermo shaker at  $37^\circ\text{C}$  and 300 rpm, together with different concentrations of uranyl acetate: (A) 0; (B) 0.2; (C) 2; and (D)  $20 \mu\text{M}$ . White scale bars are either 2 (A,C) or 1  $\mu\text{m}$  (B,D).

(Figure 2D). These results show that  $\text{UO}_2^{2+}$  ions inhibit the formation of  $A\beta$  amyloid fibrils in a concentration-dependent manner, with complete inhibition at stoichiometric uranyl/ $A\beta_{40}$  ratios.

## 2.3. NMR Spectroscopy on Uranyl Binding to $A\beta_{40}$

**Monomers.** High-resolution nuclear magnetic resonance (NMR) experiments were conducted to investigate if there were residue-specific molecular interactions between uranyl ions and monomeric  $A\beta_{40}$  peptides. Figure 3 shows 2D  $^1\text{H}$ ,  $^{15}\text{N}$ -HSQC spectra for the amide cross-peak region for  $92 \mu\text{M}$   $^{15}\text{N}$ -labeled  $A\beta_{40}$  peptides, at either pH 7.3 or pH 5.1, recorded before and after the addition of uranyl acetate.

At pH 7.3, addition of first  $46 \mu\text{M}$  and then  $92 \mu\text{M}$  uranyl ions (1:2 and 1:1 uranyl/ $A\beta_{40}$  ratio, respectively) induces a concentration-dependent loss of amide cross-peak intensity (Figure 3A). The intensity loss is uniformly distributed across the peptide sequence, which shows that the uranyl ions do not bind to specific residues of the  $A\beta_{40}$  monomer. Instead, the observed binding is likely driven by general electrostatic interactions between the cationic uranyl ions and the anionic  $A\beta$  peptides. The loss of cross-peak intensity is probably caused by several factors, such as paramagnetic quenching effects<sup>99,100</sup> and intermediate (on the NMR time-scale) chemical exchange between free  $A\beta_{40}$  peptides and the  $A\beta_{40}$  uranyl complex, similar to the effects observed when  $\text{Cu(II)}$ ,  $\text{Ni(II)}$ , and  $\text{Zn(II)}$  ions bind to  $A\beta$  peptides.<sup>117–120</sup> In addition, the uranyl ions likely promote the formation of  $A\beta$  aggregates that either precipitate out of the solution or are too large and heterogeneous to produce distinct NMR signals.<sup>119,120</sup> As no NMR signals are observed for the  $A\beta_{40}$

**Table 1.** Kinetic Parameters for  $A\beta_{40}$  Aggregation in the Presence of Different Concentrations of Uranyl Acetate, Derived from the ThT Fluorescence Curves Shown in Figure 1<sup>a</sup>

uranyl ions	$0 \mu\text{M}$	$0.04 \mu\text{M}$	$0.2 \mu\text{M}$	$0.4 \mu\text{M}$	$2 \mu\text{M}$	$20 \mu\text{M}$
$t_{1/2}$ (h)	$3.5 \pm 0.3$	$3.1 \pm 1.5$	$6.7 \pm 1.4$	n/a	n/a	n/a
$T_{\text{lag}}$ (h)	$2.4 \pm 0.2$	$2.0 \pm 1.1$	$5.2 \pm 0.9$	n/a	n/a	n/a
$\Delta\text{ThT}$ (a.u.)	2067	1286	958	101	0	0

<sup>a</sup>Aggregation half-time ( $t_{1/2}$ ) and lag time ( $T_{\text{lag}}$ ) were obtained from fitting the ThT curves to eq 1. The increase in ThT fluorescence ( $\Delta\text{ThT}$ ) is presented in arbitrary fluorescence units (a.u.).

**Figure 3.** 2D NMR  $^1\text{H}$ ,  $^{15}\text{N}$ -HSQC-spectra at 5 °C showing titrations of uranyl acetate to 92  $\mu\text{M}$  monomeric  $^{15}\text{N}$ -labeled  $\text{A}\beta_{40}$  peptides in 20 mM MES buffer at either pH 7.3 (A) or pH 5.1 (B). Blue cross-peaks: 84  $\mu\text{M}$   $\text{A}\beta_{40}$  only. Red cross-peaks: 1:2 uranyl/ $\text{A}\beta_{40}$ . Yellow cross-peaks (pH 7.3 only): 1:1 uranyl/ $\text{A}\beta_{40}$ . The peak intensities in the bar charts show ratios between the cross-peak intensities with added uranyl ions relative to the intensities before the addition of uranyl ions, i.e.,  $I/I_0$ .

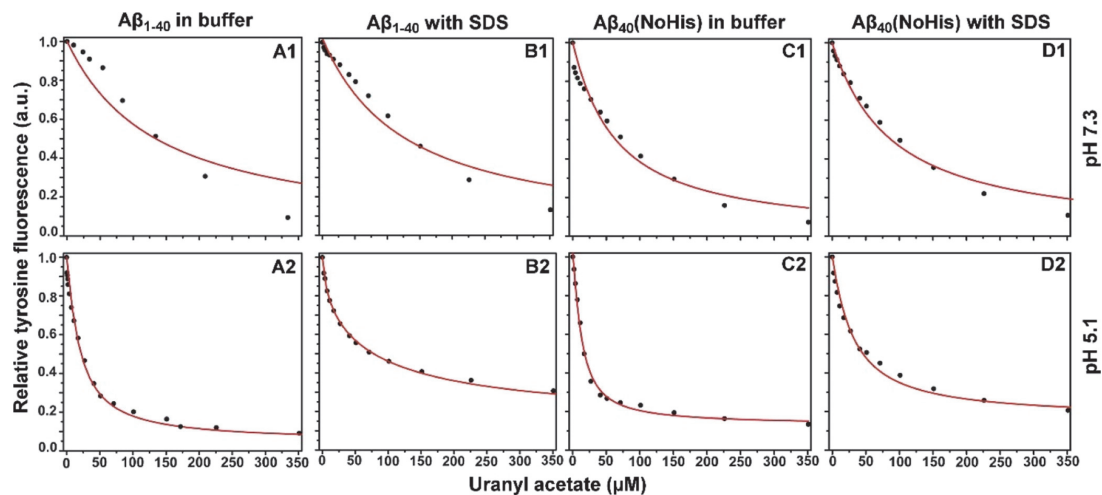

aggregates, nothing can be concluded about the binding configurations for uranyl ions in complex with such aggregates.

At pH 5.1, addition of uranyl ions again induces a uniform loss of amide cross-peak intensity (Figure 3B). Unexpectedly, the effect is stronger at pH 5.1 than at pH 7.3: addition of 46  $\mu\text{M}$  uranyl acetate (1:2 uranyl/ $\text{A}\beta_{40}$  ratio) at pH 5.1 decreases the cross-peak intensity approximately as much as the addition of 92  $\mu\text{M}$  uranyl acetate (1:1 ratio) at pH 7.3 (Figure 3). This suggests stronger binding of the uranyl ions at an acidic pH. When comparing the NMR spectra without added uranyl ions at neutral (Figure 3A) and acidic (Figure 3B) pH, NMR cross-peaks for a few additional residues (e.g., D1, A2, H6, H13, and H14) became visible at acidic pH (Figure 3B), probably due to slower proton exchange at this pH.<sup>119</sup>

**2.4. Fluorescence Measurements of Uranyl  $\text{A}\beta$  Binding Affinity.** Uranyl ions were found to quench the intrinsic

fluorescence of the Tyr10 residue in the  $\text{A}\beta$  peptide, similar to, e.g., Cu(II) ions.<sup>121–123</sup> Measurements of the Tyr10 fluorescence during titrations with uranyl acetate were therefore used to quantify binding affinities for  $\text{A}\beta\text{-UO}_2^{2+}$  complexes under different conditions. The resulting titration/binding curves are shown in Figure 4. Fitting eq 2 to these curves produced the apparent dissociation constants ( $K_D^{\text{APP}}$ ) shown in Table 2.

For  $\text{A}\beta_{40}$  at pH 7.3, the titration data clearly deviate from the binding model, both for the measurements in buffer only (Figure 4A1) and in the presence of sodium dodecyl sulfate (SDS) micelles (Figure 4B1). Because of these deviations, the derived dissociation constants should not be trusted. As eq 2 is based on a model that assumes a single binding site, a possible explanation for this deviation is the binding of uranyl ions to multiple locations on the  $\text{A}\beta_{40}$  peptide under these conditions.

**Figure 4.** Fluorescence intensity curves for  $A\beta$  residue Tyr10, showing titrations of 20  $\mu\text{M}$   $A\beta_{40}$  peptide (A,B) or 20  $\mu\text{M}$   $A\beta_{40}$  (NoHis) mutant (C,D) with uranyl acetate in 20 mM MES buffer, either at pH 7.3 (1st row) or at pH 5.1 (2nd row). For (B,D), micelles of 50 mM SDS were added to the samples.

**Table 2.** Apparent Dissociation Constants ( $K_D^{\text{APP}}$ ) in  $\mu\text{M}$  for Uranyl- $A\beta$  Complexes, Obtained by Fitting Fluorescence Titration Curves to eq 2 (Figure 4; Three Replicates per Condition)

	$A\beta_{40}$				$A\beta_{40}$ (NoHis)			
	1	2	3	average	1	2	3	average
pH 7.3	130	141	148	$140 \pm 8$	62	86	79	$76 \pm 11 \mu\text{M}$
pH 7.3 + 50 mM SDS	206	252	251	$236 \pm 22$	119	124	116	$120 \pm 4 \mu\text{M}$
pH 5.1	14.0	13.7	21.3	$16.3 \pm 4$	2.3	2.8	4.0	$3.0 \pm 1 \mu\text{M}$
pH 5.1 + 50 mM SDS	21.8	21.7	27.4	$23.6 \pm 3$	22.3	30.7	27.9	$27.0 \pm 4 \mu\text{M}$

At pH 5.1, the binding curves follow the model very well (Figure 4A2,B2), yielding reliable  $K_D^{\text{APP}}$  values of 16.3  $\mu\text{M}$  for  $A\beta_{40}$  in buffer and 23.6  $\mu\text{M}$  for  $A\beta_{40}$  bound to SDS micelles (Table 2). The main difference from the measurements at neutral pH is that the three His residues in the  $A\beta$  peptide become protonated at lower pH as their  $\text{p}K_a$  values are around 6.8.<sup>124</sup> Because protonated His residues are unlikely to interact with positive ions such as  $\text{UO}_2^{2+}$ , it is possible that binding interactions between uranyl ions and uncharged His residues are responsible for the deviations from the single-site binding scheme observed at pH 7.3 (Figure 4A1,B1).

The binding curves for the  $A\beta_{40}$  (NoHis) mutant at pH 7.3 follow the model rather well (Figure 4C1,D1), producing  $K_D^{\text{APP}}$  values of 76  $\mu\text{M}$  in buffer and 120  $\mu\text{M}$  in the presence of SDS micelles (Table 2). At pH 5.1, the overlap with the fitted curve is even better (Figure 4C2,D2), and here, the  $K_D^{\text{APP}}$  values are 3.0  $\mu\text{M}$  in buffer and 27  $\mu\text{M}$  in the presence of SDS micelles. With these results, some comparisons can be made.

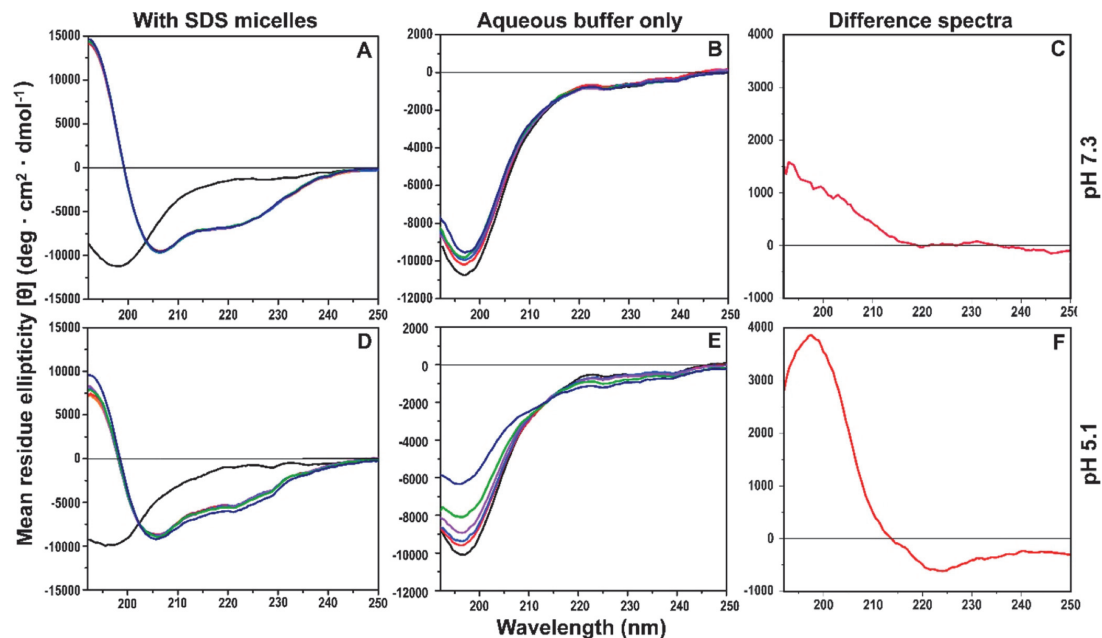

For both peptide versions, the uranyl ions display stronger binding at low pH. Even though reliable binding constants could not be obtained for  $A\beta_{40}$  at pH 7.3, it is clear from the measurement data that binding is overall stronger at pH 5.1 (Figure 4A,B). Addition of SDS micelles generally makes the binding weaker (Table 2). This effect is likely related to the SDS molecules being negatively charged, thereby competing for binding to the cationic uranyl ions. The strongest uranyl binding is observed for the  $A\beta_{40}$  (NoHis) mutant at pH 5.1 (3.0  $\mu\text{M}$ ), while the weakest binding is observed for  $A\beta_{40}$  at pH

7.3. It therefore appears that neutral (i.e., non-protonated) His residues might interfere with uranyl binding under the experimental conditions used.

## 2.5. CD Spectroscopy on the $A\beta$ Secondary Structure.

Circular dichroism (CD) spectroscopy was used to investigate the possible effects of uranyl ions on the secondary structure of  $A\beta_{40}$  peptides, both in aqueous buffer and in the presence of SDS micelles that mimic a membrane environment. The CD spectra for  $A\beta_{40}$  monomers in aqueous buffer display spectra with minima around 196–198 nm (Figure 5B,E), which is typical for a random coil conformation. At pH 5.1, addition of uranyl ions to  $A\beta_{40}$  induces a two-step structural transition as the CD signal changes in a concentration-dependent manner around an isodichroic point at approximately 214 nm (Figure 5E). The difference spectrum (Figure 5F) shows that the structural transition is a conversion from random coil to  $\beta$ -sheet. At pH 7.3, the structural effect induced by the uranyl ions is weaker, and it is unclear if an isodichroic point is present (Figure 5B). The difference spectrum is not conclusive but might represent  $\beta$ -sheet conformation (Figure 5C).

In the presence of SDS micelles, the CD signals for  $A\beta_{40}$  peptides display minima around 208 and 222 nm (Figure 5A,D), which is characteristic for the  $\alpha$ -helical secondary structure. This is in line with previous reports that the central and C-terminal  $A\beta$  regions adopt  $\alpha$ -helical conformations in membrane-like environments.<sup>19,122,125,126</sup> At pH 7.3, addition of uranyl ions induces no changes at all in the  $A\beta_{40}$  CD spectrum with SDS (Figure 5A). At pH 5.1, however, the

**Figure 5.** CD spectroscopic titrations of  $10 \mu\text{M}$   $A\beta_{40}$  with uranyl acetate in  $20 \text{ mM}$  sodium phosphate buffer at  $20 \text{ }^\circ\text{C}$ , carried out in the presence of  $50 \text{ mM}$  SDS at pH 7.3 (A) or pH 5.1 (D), or in aqueous buffer only at pH 7.3 (B) or pH 5.1 (E). First, spectra were recorded for  $A\beta_{40}$  in buffer for all samples (black lines). Then,  $50 \text{ mM}$  SDS detergent was added to the samples in (A,D) (orange lines). To all samples, uranyl acetate was added in steps of 2, 6, 16, 56, and  $256 \mu\text{M}$  (ruby red, ultramarine blue, plum purple, lime green, and navy blue lines, respectively). For the titrations in aqueous buffer, shown in (B,E), the difference spectra shown in (C,F) were created by subtracting the measurements with  $256 \mu\text{M}$  added uranyl from the measurements without uranyl, at pH 7.3 (C) and pH 5.1 (F).

**Figure 6.** Fluorescence emission spectra of  $10 \mu\text{M}$   $A\beta_{40}$  peptides in  $20 \text{ mM}$  MES buffer, pH 7.3, incubated with  $100 \mu\text{M}$  EDTA (A) or with  $100 \mu\text{M}$  uranyl acetate (B). Black line—0 h and red line—24 h.

uranyl ions induce systematic changes in the CD spectra around an isodichroic point at approximately  $203 \text{ nm}$  (Figure 5D). This is the same wavelength as where the CD spectrum for  $A\beta_{40}$  peptides in aqueous solution (i.e., random coil structure) crosses the CD spectrum for  $A\beta_{40}$  peptides in SDS micelles (i.e.,  $\alpha$ -helical structure), when no uranyl ions are present (Figure 5D). Taken together, these observations indicate that uranyl ions at pH 5.1 induce a structural conversion from  $\alpha$ -helix to a random coil in  $A\beta_{40}$  peptides in SDS micelles. Also, the changes in CD intensity at other wavelengths are consistent with the formation of a random coil

structure, even though the overall changes are small and difficult to interpret conclusively (Figure 5D). The overall larger structural effects induced by uranyl ions at acidic pH, compared to neutral pH, both in aqueous solution (Figure 5B,E) and in SDS micelles (Figure 5A,D), support the NMR (Figure 3) and fluorescence (Figure 4) spectroscopy results that the uranyl ions bind stronger to  $A\beta_{40}$  peptides at acidic pH.

**2.6. Dityrosine Cross-Link Formation.** Fluorescence measurements were carried out to investigate if uranyl ions could induce the formation of covalent dityrosine cross-links in

$A\beta$  peptides via the generation of ROS, similar to what has been observed for redox-active Cu(II) ions<sup>35,127–129</sup> and Ni(II) ions.<sup>118</sup> Two samples of  $A\beta_{40}$  peptides were studied. The control sample contained 100  $\mu\text{M}$  EDTA to remove possible contaminating metal ions that could promote dityrosine formation. The other sample contained 100  $\mu\text{M}$  uranyl acetate. For both samples, the fluorescence spectra are virtually identical before and after 24 h of incubation (Figure 6). Specifically, no peak around 410 nm, indicative of dityrosine,<sup>129,130</sup> has emerged. The signal around 350 nm is a water Raman peak, which is useful for reference purposes as it does not change with the sample composition. These results clearly show that uranyl ions do not induce the formation of dityrosine cross-links under the experimental conditions employed here.

**2.7. BN-PAGE Analysis of  $A\beta_{42}$  Oligomer Formation and Stability.** Blue native polyacrylamide gel electrophoresis (BN-PAGE) analysis and Fourier-transform infrared (FTIR) analysis (below) were used to investigate possible effects of uranyl ions on  $A\beta$  oligomer formation. Because  $A\beta_{40}$  peptides do not form stable oligomers,  $A\beta_{42}$  peptides together with SDS detergent were used to create oligomers that remained stable for over a week. The  $A\beta_{42}$  oligomers were created with two different concentrations of stabilizing SDS molecules, 80–100  $\mu\text{M}$  of  $A\beta_{42}$  peptides and 0–1000  $\mu\text{M}$  of uranyl acetate, as described in Section 5.2.

The BN-PAGE analysis shows that in 0.05% SDS (1.7 mM) without uranyl acetate, larger oligomers with a molecular weight (MW) around 55–60 kDa are formed (Figure 7, lane 3).

**Figure 7.** BN-PAGE gel showing the effects of different concentrations of uranyl acetate on the formation of SDS-stabilized  $A\beta_{42}$  oligomers (formed with 80–100  $\mu\text{M}$  peptide). Lane 1: reference ladder. Lane 2:  $A\beta_{42}$  monomers. Lanes 3–6:  $A\beta\text{O}_{0.05\% \text{SDS}}$  oligomers (likely dodecamers) prepared with 0, 10, 100, and 1000  $\mu\text{M}$  uranyl ions, respectively. Lanes 7–10:  $A\beta\text{O}_{0.2\% \text{SDS}}$  oligomers (likely tetramers) prepared with 0, 10, 100, and 1000  $\mu\text{M}$  uranyl ions, respectively.

These larger oligomers, abbreviated  $A\beta\text{O}_{0.05\% \text{SDS}}$ , most likely contain twelve  $A\beta_{42}$  peptides and display a globular morphology, which is why they are sometimes called globulomers.<sup>131</sup> In the presence of different concentrations of uranyl acetate, no well-defined uniform oligomers were observed. Instead, the bands on the BN-PAGE gel appear smeared, indicating a heterogeneous size distribution of the

formed oligomers (Figure 7, lanes 4–6). This disruptive effect is already very strong at the lowest concentration (10  $\mu\text{M}$ ) of added uranyl ions.

In 0.2% SDS (6.9 mM), small  $A\beta_{42}$  oligomers with a MW around 16–20 kDa are formed (Figure 7, lane 7). These oligomers, abbreviated  $A\beta\text{O}_{0.2\% \text{SDS}}$ , likely contain a large fraction of tetramers.<sup>131,132</sup> Preparation of these oligomers in the presence of increasing uranyl concentrations (10, 100, and 1000  $\mu\text{M}$ ) yields oligomer bands that are weaker at the intermediate uranyl concentrations and weakest at the highest concentration, indicating gradually lower amounts of stable  $A\beta\text{O}_{0.2\% \text{SDS}}$  oligomers (Figure 7, lanes 8–10). Thus, for the formation of the smaller  $A\beta\text{O}_{0.2\% \text{SDS}}$  oligomers at the higher SDS concentration, the effect of uranyl ions is less disruptive and clearly concentration-dependent compared to the effect on the larger  $A\beta\text{O}_{0.05\% \text{SDS}}$  oligomers (Figure 7).

**2.8. FTIR Spectroscopy Reflecting the  $A\beta_{42}$  Oligomer Structure.** The secondary structures of  $A\beta_{42}$  oligomers formed with different SDS and uranyl concentrations were studied with FTIR spectroscopy, where the amide I region (1700–1600  $\text{cm}^{-1}$ ) is very sensitive to changes in the protein backbone conformation, including differences in  $\beta$ -sheet structures.<sup>133–135</sup> When prepared in the absence of uranyl acetate, both types of  $A\beta_{42}$  oligomers (i.e.,  $A\beta\text{O}_{0.05\% \text{SDS}}$  and  $A\beta\text{O}_{0.2\% \text{SDS}}$ ) produce two major bands in the amide I region: a high-intensity band near 1630  $\text{cm}^{-1}$  and a smaller one near 1686  $\text{cm}^{-1}$ .<sup>132</sup> This split pattern of IR bands in the amide I region is typical for anti-parallel  $\beta$ -sheet structures.<sup>136–138</sup>

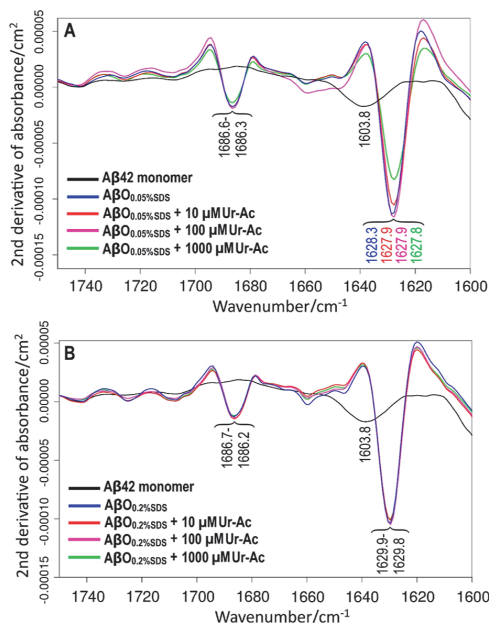

For  $A\beta\text{O}_{0.05\% \text{SDS}}$  oligomers in PBS buffer, the  $\beta$ -sheet main band shows a band shift due to uranyl acetate: the main band is observed at 1628.3  $\text{cm}^{-1}$  without uranyl acetate, but shifts down to 1627.8  $\text{cm}^{-1}$  in the presence of 1 mM (1000  $\mu\text{M}$ ) uranyl acetate (Figure 8A). In contrast to the  $A\beta\text{O}_{0.05\% \text{SDS}}$  oligomers, the spectrum of the  $A\beta\text{O}_{0.2\% \text{SDS}}$  oligomers (resolved at 1629.9  $\text{cm}^{-1}$ , Figure 8B) is not significantly affected by the uranyl acetate concentration (1629.8  $\text{cm}^{-1}$  at 0.01, 0.1, and 1 mM uranyl acetate) (Figure 8B). This result also indicates that band positions can be determined with an accuracy of 0.1  $\text{cm}^{-1}$ , which is supported by our study of Li(I) ion effects,<sup>139</sup> where at both SDS concentrations, the standard deviation of the band positions for four Li(I) ion concentrations (0, 0.1, 1, and 10 mM) was 0.12  $\text{cm}^{-1}$  and the band positions at zero and 10 mM Li(I) differed by less than 0.1  $\text{cm}^{-1}$ .

These observations agree with the BN-PAGE results, which showed clear small oligomer bands for all uranyl concentrations at the higher SDS concentration, but extended smears instead in the presence of uranyl acetate for the lower SDS concentration. The results indicate again that the  $A\beta_{42}$  globulomers produced at the lower SDS concentration are more sensitive to uranyl-induced effects.

### 3. DISCUSSION

Uranium is a well-known neurotoxicant,<sup>39</sup> but the underlying molecular mechanisms and a possible role of U in neurodegenerative diseases remain unclear.<sup>49,91</sup> For AD, several studies have investigated how  $A\beta$  peptides interact with various metal ions<sup>30,47,118,139–142</sup> and with small cationic molecules.<sup>28,143</sup> We here interpret the current results on  $A\beta$ –uranyl interactions in the light of this earlier work.

**3.1. Effects of Uranyl Ions on  $A\beta_{40}$  Aggregation.** The ThT fluorescence curves (Figure 1) and TEM images (Figure 2) show that uranyl ions have a concentration-dependent inhibitory effect on the fibrillation of  $A\beta_{40}$  peptides at

**Figure 8.** Second derivatives of infrared absorbance spectra for 80–100  $\mu\text{M}$  SDS-stabilized  $A\beta_{42}$  oligomers formed in the absence (blue) and presence of 0.01 mM (red), 0.1 mM (purple), and 1 mM (green) uranyl acetate. The results are shown for larger  $A\beta_{42}$  oligomers formed with 0.05% SDS (A) and for smaller  $A\beta_{42}$  globulomers formed with 0.2% SDS (B).

physiological pH. Instead of forming proper amyloid fibrils, the  $A\beta_{40}$  peptides form non-fibrillar amorphous aggregates (clumps) already at a 1:1 uranyl/ $A\beta_{40}$  ratio (Figure 2). This effect is seen both in the TEM images and the ThT fluorescence experiments, even though the sample conditions are somewhat different (i.e., the TEM samples did not contain ThT dye and were incubated in Eppendorf tubes on a thermo shaker). Thus, the uranyl ions do not prevent the  $A\beta_{40}$  peptides from aggregating but rather direct the aggregation process toward non-fibrillar end-products. Similar effects on the  $A\beta$  aggregation pathways have previously been observed for other small cationic molecules and heavy metal ions such as Hg(II), Ni(II), Pb(II), and Pb(IV).<sup>47,118,143</sup> As small oligomeric aggregates of  $A\beta$  peptides are considered to be the main toxic species in AD pathology,<sup>2,11</sup> the finding that uranyl ions can modulate  $A\beta$  aggregation might be relevant for understanding AD progression and pathogenesis.

**3.2. Binding of Uranyl Ions to  $A\beta_{40}$  Peptides.** The NMR results show that uranyl ions have no obvious residue-specific binding to  $A\beta_{40}$  peptides (Figure 3). Because of the strong covalent O=U=O bonds in the uranyl ion, it is mainly the central U(VI) atom that interacts with other molecules.<sup>144</sup> Thus, the uranyl- $A\beta$  binding is probably mediated via non-specific electrostatic interactions between the positive U(VI) atom and negative  $A\beta$  residues, such as Asp1, Asp7, Asp23, Glu3, Glu11, and Glu22. This is similar to  $A\beta$  binding to Mn(II) and Pb(II) ions,<sup>3,140</sup> but different from numerous small cationic species that display residue-specific interactions with  $A\beta$  peptides, such as polyamines<sup>28</sup> and Cu(II), Ni(II), Pb(IV), and Zn(II) ions.<sup>3,117–119</sup>

The results of the NMR measurements indicate that the  $A\beta$  binding of uranyl ions is stronger at acidic pH (Figure 3), which is confirmed by the fluorescence measurements of uranyl- $A\beta$  binding affinity (Figure 4) and also by the CD spectroscopy results (Figure 5). At pH 5.1, the apparent binding affinity of uranyl ions is  $16.3 \pm 4 \mu\text{M}$  to  $A\beta_{40}$  peptides and  $3.0 \pm 1 \mu\text{M}$  to the  $A\beta_{40}$  (NoHis) mutant (Table 2). At neutral pH, the binding is about a magnitude weaker (Table 2) and also less well-defined (Figure 4). This is counter-intuitive. The main chemical difference at lower pH is that the  $A\beta$  His residues become protonated as they have  $pK_a$  values around 6.8 in short peptides.<sup>124</sup> It stands to reason that  $A\beta$  peptides with positively charged His residues should be less prone to interact with positive metal ions, as has been shown for, e.g., Cu(II) and Zn(II) ions.<sup>119</sup> On the other hand, the uranyl ion is a weak acid that undergoes hydrolysis, and the first  $pK_a$  is around 4–5.<sup>145,146</sup> Thus, at pH 5.1, the uranyl ions may be mixed with monomeric and dimeric hydroxide species. At pH 7.3, additional species might be present, such as the single-charged trimer  $[(\text{UO}_2)_3(\text{OH})_3]^+$ . It is possible that such heterogeneity, which is likely more pronounced at neutral pH, could help explain the somewhat unexpected uranyl titration results.

The Tyr10 fluorescence measurements (Figure 4) show that the uranyl  $A\beta$  binding affinity increases at lower pH values and also when the three His residues are replaced by Ala residues (Table 2). In fact, the weakest binding is observed for  $A\beta_{40}$  at pH 7.3, and the strongest binding is observed for the  $A\beta_{40}$  (NoHis) mutant at pH 5.1 (Table 2). This trend is observed for  $A\beta$  samples both in aqueous buffer and in SDS micelles. It strongly suggests that the presence of uncharged His sidechains interferes with uranyl binding to  $A\beta$  peptides (Table 2). This tentative conclusion is supported by the shape of the fluorescence data curves, which are more uniform and better fit the single-binding-site model (eq 2), when the uncharged His residues H6, H13, and H14 are replaced with Ala residues in the  $A\beta_{40}$  (NoHis) mutant (Figure 4). In addition, at acidic pH, the uranyl binding is stronger both to the wild-type (wt)  $A\beta_{40}$  peptide and to the  $A\beta_{40}$  (NoHis) mutant. In the latter case, the effect is clearly not caused by His protonation as these residues are missing in the mutant peptide. Thus, the His residues are not the only factor responsible for the unusual properties of uranyl- $A\beta$  binding. As discussed above, formation of uranyl hydroxide species is likely another confounding factor. The molecular details of uranyl- $A\beta$  binding should therefore be further explored in future studies.

Because toxic  $A\beta$  aggregates appear to form in membrane environments,<sup>147</sup> and as membrane disruption might be one of the toxic mechanisms of  $A\beta$  aggregates,<sup>148</sup> it is important to clarify how  $A\beta$  interacts with uranyl ions also in a membrane environment. Here, we used SDS micelles as a simple membrane model. Even though such micelles are different from the phospholipid bilayers present in cell membranes, they do share some properties with real membranes, while being much more suitable for various spectroscopy measurements, including NMR.<sup>125,126</sup> Our fluorescence spectroscopy measurements showed that the uranyl binding affinities decrease slightly when SDS micelles are present in the sample for all  $A\beta$  variants and conditions (Figure 4 and Table 2). This effect is probably caused by the anionic SDS micelles competing for binding to the cationic uranyl ions. Similar results have earlier been obtained for  $A\beta$  binding to other metal ions, such as

Cu(II), Hg(II), and Ni(II), in the presence of SDS micelles.<sup>47,118,122</sup>  $A\beta$  peptides are known to insert only their central and C-terminal regions into an SDS micelle, while the negatively charged N-terminal region is positioned outside the micelle where it is free to interact with, e.g., cations.<sup>118,122</sup> Thus, it appears that  $A\beta$  peptides can (sometimes) bind uranyl ions mainly via their N-terminal part in a membrane environment. We may speculate that when multiple  $A\beta$  peptides are present in the membrane, a single uranyl ion might bind to the N-termini from two or more  $A\beta$  peptides, thereby bringing the peptides together and promoting aggregation.

**3.3. Effects of Uranyl Ions on the  $A\beta_{40}$  Peptide Structure.** In an aqueous buffer at pH 5.1, the CD spectroscopy measurements show that uranyl ions induce a two-state structural transition in the  $A\beta_{40}$  peptides, from random coil to  $\beta$ -sheet structure (Figure SE,F). At pH 7.3, a weaker structural transition is observed, which might be a similar conversion into a  $\beta$ -sheet structure (Figure SB,C). Earlier studies have shown that such structural changes can be induced also by metal ions such as Cu(II), Ni(II), and Zn(II).<sup>118,119</sup> Because  $A\beta$  aggregates typically consist of peptides in  $\beta$ -sheet conformation,<sup>18</sup> this type of  $\beta$ -sheet structure formation likely promotes  $A\beta$  aggregation.

SDS micelles constitute a simple membrane model,<sup>125,126</sup> and the central and C-terminal regions of  $A\beta$  peptides are known to insert themselves into such micelles and adopt  $\alpha$ -helical conformations.<sup>19,126</sup> In the presence of SDS micelles, uranyl ions have no effect on the  $A\beta_{40}$  peptide conformation at pH 7.3 (Figure SA). However, a weak structural transition is observed at pH 5.1, possibly involving the formation of random coils (Figure SD). Previous studies have found that metal ions that bind to  $A\beta$  peptides mainly via the His residues, such as Cu(II), Ni(II), and Zn(II) ions, can induce altered coil-coil interactions in  $A\beta$  peptides positioned in SDS micelles.<sup>118,122</sup> No such alterations in the  $\alpha$ -helical structure were observed upon the addition of uranyl ions (Figure SA,D).

No dityrosine cross-links were observed after  $A\beta_{40}$  peptides had been incubated together with uranyl acetate (Figure 4). Earlier studies have shown that redox-active metal ions such as Cu(II) and Ni(II) can induce the formation of dityrosine cross-links in amyloid peptides via redox-cycling of, e.g., the Cu(I)/Cu(II) redox pair, which generates harmful oxygen radicals via Fenton-like chemistry.<sup>35,37,38,118,129</sup> For short peptides with only one Tyr residue in the amino acid sequence, such as  $A\beta$  and amylin, dityrosine formation must involve two peptides, which then become linked to form a dimer.<sup>129</sup> As Cu(II) and Ni(II) bind  $A\beta$  peptides mainly via the His6, His13, and His14 residues, it is likely that these metal ions can promote  $A\beta$  aggregation by coordinating multiple His residues from more than one  $A\beta$  peptide.<sup>141,149</sup> Cu(II) and Ni(II) ions may therefore promote dityrosine formation not only by creating oxygen radicals but also by connecting two  $A\beta$  molecules and positioning their Tyr10 residues close to each other. It is known that the U(VI) ion in uranyl can be reduced to lower valency states such as U(IV) under appropriate reducing conditions.<sup>144,150</sup> Thus, as uranyl acetate has been found to induce oxidative stress in isolated cells,<sup>97</sup> the uranyl ions are likely redox-active under physiological conditions. We therefore speculate that the reason why uranyl ions do not promote dityrosine formation in  $A\beta_{40}$  peptides (Figure 4) is the weak and non-specific binding under the experimental conditions used (Figures 7, 8, and Table 2).

### 3.4. Effects of Uranyl Ions on $A\beta_{42}$ Oligomers.

Although most of the measurements carried out in this study were performed on  $A\beta_{40}$  monomers, it is also of interest to investigate the possible effects of uranyl ions on  $A\beta$  oligomers. Because  $A\beta_{40}$  peptides do not form stable oligomers, BN-PAGE and FTIR studies were carried out on  $A\beta_{42}$  oligomers stabilized by SDS detergent. The BN-PAGE experiments clearly show that uranyl ions interfere with the formation of homogeneous  $A\beta_{42}$  oligomers (Figure 7). This is further supported by the FTIR measurements, where the position of the  $\beta$ -sheet main band is downshifted when increasing concentrations of uranyl ions are present during oligomer formation (Figure 8). The uranyl effect is more pronounced on the larger and mainly dodecameric  $A\beta_{42}$  oligomers, which are formed in the presence of 0.05% SDS. The spectral changes observed with uranyl ions are consistent with the previously observed effects of Ni(II) ions.<sup>118</sup> However, only 10  $\mu$ M of divalent uranyl ions (Figure 7, Lane 4) but 500 mM of divalent Ni(II) ions<sup>118</sup> are required for full disruption of homogeneous  $A\beta_{42}$  oligomers, even though Ni(II) ions display a stronger binding affinity for  $A\beta$  peptides than uranyl ions at neutral pH (Figures 7, 8 and Table 2). In general, the effects of uranyl ions on  $A\beta$  oligomerization qualitatively resemble those of other transition metal ions, including Ni,<sup>118</sup> more than those of monovalent alkali ions, such as Li.<sup>139</sup> Such conclusions are consistent with the theoretical findings regarding the relative propensities of different metal ions for interactions with polypeptides.<sup>151</sup>

**3.5. Medical Implications.** Our current results show that uranyl ions induce structural changes in  $A\beta$  monomers and  $A\beta$  oligomers and inhibit  $A\beta$  fibrillization and homogeneous oligomer formation already at sub-stoichiometric concentrations. It is unclear how these uranyl interactions may influence (or not) the toxicity of  $A\beta$  oligomers or the  $A\beta$ -induced pathology in AD patients. Furthermore, no link has been established between uranium/uranyl exposure and AD incidence. On the other hand, very few people have investigated such possible links. The current results show that uranyl ions affect  $A\beta$  peptide aggregation in similar ways as Pb and Hg ions, and Pb and Hg exposure might be linked to the development of AD and other neurodegenerative diseases.<sup>3,47</sup> Given these similar molecular interactions, it could be worthwhile to conduct cell studies, animal studies, and epidemiological studies on AD patients to find out if exposure to uranium/uranyl might induce AD. However, even if such an effect does exist, U is a well-known toxic metal, and it is possible that people exposed to U will suffer more immediate harmful health effects that will mask a slowly progressing dementia. The molecular mechanisms for the chemical toxicity of U are not fully understood. Our current results show that even low concentrations of uranyl can induce unstructured protein aggregation in  $A\beta$  peptides and, most likely, also in other peptides and proteins. Thus, a general toxic mechanism of uranyl ions could be to modulate protein folding, misfolding, and aggregation.

## 4. CONCLUSIONS

Uranyl ions,  $UO_2^{2+}$ , bind to  $A\beta_{40}$  peptides via non-specific electrostatic interactions, with an apparent binding affinity of  $16.3 \pm 4 \mu$ M at pH 5.1. Uranyl binding is weaker and less uniform at neutral pH, possibly because of interference from His sidechains and from other uranyl species such as hydroxides. The uranyl ions inhibit  $A\beta$  fibrillization and

oligomer formation in a concentration-dependent manner, with clear effects already at sub-stoichiometric concentrations, and also induce structural changes in  $A\beta$  monomers and  $A\beta$  oligomers. A general toxic mechanism of uranyl ions could be to modulate protein folding, misfolding, and aggregation.

## 5. MATERIALS AND METHODS

**5.1. Materials.** SDS detergent, 2-(*N*-morpholino)ethanesulfonic acid (MES) hydrate, sodium phosphate, depleted uranyl acetate, and dimethyl sulfoxide (DMSO) were all purchased from Sigma-Aldrich (USA).

Synthetic lyophilized wt  $A\beta$  (1–42) peptides, abbreviated as  $A\beta_{42}$ , with the primary sequence DAEFR<sub>3</sub>HDSGY<sub>10</sub>EVHHQ<sub>13</sub>KLTVFF<sub>20</sub>AEDVG<sub>25</sub>SNKGA<sub>30</sub>IIGLM<sub>35</sub>VGGVV<sub>40</sub>IA, were purchased from JPT Peptide Technologies (Germany). Two recombinant  $A\beta$  variants were purchased as lyophilized powder from AlexoTech AB (Umeå, Sweden), namely, the  $A\beta_{40}$  peptide and the  $A\beta_{40}$  (H6A, H13A, and H14A) triple-mutant, which in the following is referred to as the  $A\beta_{40}$  (DimHis) mutant. The  $A\beta_{40}$  peptide was also purchased uniformly single-labeled with <sup>15</sup>N isotopes. All  $A\beta_{40}$  peptide variants were stored at –80 °C until use. Before measurements, they were dissolved in 10 mM NaOH and then sonicated in an ice bath for 5 min to avoid preformed aggregates. The samples were then diluted in either sodium phosphate buffer at pH 7.3 or in MES buffer at pH 7.3 or 5.1. The peptide concentrations were initially estimated from the weight of the dry powder and then more accurately determined with a NanoDrop spectrophotometer.

**5.2. Preparation of  $A\beta_{42}$  Oligomers.** Treatment of  $A\beta_{42}$  peptides with low concentrations ( $\leq 7$  mM) of SDS, i.e., below the critical micelle concentration for SDS, which is 8.2 mM in water at 25 °C,<sup>152</sup> leads to the formation of stable and homogeneous  $A\beta_{42}$  oligomers of certain sizes and conformations.<sup>131,132,153</sup> To prepare such oligomers, size exclusion chromatography (SEC) was initially used to purify synthetic  $A\beta_{42}$  peptides into monomeric form. First, 1 mg of lyophilized  $A\beta_{42}$  powder was dissolved in 250 mL of DMSO. Next, a Sephadex G-250 HiTrap desalting column (GE Healthcare, Uppsala) was equilibrated with a 5 mM NaOH solution (pH = 12.3) and washed with a solution of 10–15 mL of 5 mM NaOD, pD = 12.7.<sup>154</sup> The peptide solution in DMSO was applied to the column, followed by an injection of 1.25 mL of 5 mM NaOD. The collection of peptide fractions in 5 mM NaOD on ice was started at a 1 mg/mL flow rate. Ten fractions of 1 mL volumes were collected in 1.5 mL Eppendorf tubes. The absorbance for each fraction at 280 nm was measured with a NanoDrop instrument (Eppendorf, Germany), and peptide concentrations were determined using a molar extinction coefficient of 1280 M<sup>-1</sup> cm<sup>-1</sup> for the single Tyr in  $A\beta_{42}$ .<sup>155</sup> The peptide fractions were flash-frozen in liquid nitrogen, covered with argon gas on top in 1.5 mL Eppendorf tubes, and stored at –80 °C until used. SDS-stabilized  $A\beta_{42}$  oligomers of two well-defined sizes (approximately tetramers and dodecamers) were prepared according to a previously published protocol,<sup>131</sup> but in D<sub>2</sub>O, at a 4-fold lower peptide concentration and without the original dilution step.<sup>132</sup> The reaction mixtures [100–120  $\mu$ M  $A\beta_{42}$  in PBS, containing either 0.05% (1.7 mM) SDS or 0.2% (6.9 mM) SDS] were incubated together with 0–1000  $\mu$ M uranyl acetate at 37 °C for 24 h and then flash-frozen in liquid nitrogen and stored at –20 °C for later analysis.

**5.3. Thioflavin T Aggregation Kinetics.** To monitor the effect of uranyl ions on  $A\beta_{40}$  aggregation kinetics, a FLUOstar Omega microplate reader (BMG LABTECH, Germany) was used. Samples containing 20  $\mu$ M  $A\beta_{40}$ wt, 20 mM MES buffer pH 7.3, 50  $\mu$ M thioflavin T, and different concentrations of uranyl acetate (i.e., 0, 0.04, 0.2, 0.4, 2, and 20  $\mu$ M) were added to a 384-well plate, with 35  $\mu$ L of sample in each well. Thioflavin T is a benzothiazole dye that increases in fluorescence upon binding to amyloid aggregates<sup>116</sup> and is therefore used to monitor the formation of amyloid aggregates. The ThT dye was excited at 440 nm, and ThT fluorescence emission at 480 nm was measured every 5 min. Before each measurement, the plate was shaken in orbital mode for 140 s at 200 rpm. The samples were incubated for a total of 15 h, and the assay was repeated three

times with four replicates of each condition. To determine kinetic aggregation parameters, the data was fitted to eq 1:

$$F(t) = F_0 + m_0 \cdot t + \frac{F_\infty + m_\infty \cdot t}{1 + \exp[-(t - t_{1/2})/\tau]} \quad (1)$$

Here,  $F_0$  and  $F_\infty$  are the intercepts of the initial and final fluorescence intensity baselines,  $m_0$  and  $m_\infty$  are the slopes of the initial and final baselines,  $t_{1/2}$  is the time needed to reach halfway through the elongation phase (i.e., aggregation half-time), and  $\tau$  is the elongation time constant.<sup>116</sup>

**5.4. Transmission Electron Microscopy Imaging.** Negative staining TEM images were recorded for  $A\beta_{40}$  peptides that had aggregated under the same conditions as in the ThT fluorescence studies (above). Thus, 20  $\mu$ M of  $A\beta_{40}$  in 20 mM MES buffer, pH 7.3, was incubated for 20 h on a thermo shaker at 37 °C and 300 rpm, together with 0, 0.2, 2, and 20  $\mu$ M of uranyl acetate. Then, samples of 5  $\mu$ L were put on copper grids of 200  $\mu$ m mesh size, which were covered with a Pioloform film upon which a carbon layer had been deposited and then glow-discharged with a Leica EM ACE600 carbon coater (Leica Microsystems, Germany). The  $A\beta_{40}$  samples were absorbed onto the grids for 5 min, rinsed with Milli-Q water two times, and then stained for 2 min with a 2% aqueous solution of uranyl acetate. Next, the excess stain was removed with filter paper, and the samples were left to air-dry. A digital Orius SC1000 camera was used to record TEM images in a FEI Tecnai G2 Spirit electron microscope (FEI, The Netherlands) operating at 120 kV accelerating voltage.

**5.5. Circular Dichroism Spectroscopy Measurements of the Secondary Structure.** CD measurements were carried out on a Chirascan CD spectrometer from Applied Photophysics Ltd. (U.K.). Samples containing 600  $\mu$ L of 10  $\mu$ M  $A\beta_{40}$  peptide in 20 mM phosphate buffer, at either pH 7.3 or pH 5.1, were placed in a quartz cuvette with a 2 mm pathlength. CD spectra were recorded at 20 °C between 192 and 250 nm using steps of 0.5 nm and a sampling time of 5 s per data point. Then, small volumes of uranyl acetate were titrated to the samples in steps of 2, 6, 16, 56, and finally 256  $\mu$ M. The total increase of volume upon the addition of the uranyl acetate was less than 3%. All data was processed with the Chirascan Pro-Data v.4.4.1 software (Applied Photophysics Ltd., U.K.), including smoothing with a ten-point smoothing filter. 50 mM SDS detergent was added to some of the samples as SDS micelles constitute a simple model for bio-membranes.<sup>125,126</sup>  $A\beta$  peptides are known to insert their central and C-terminal segments as  $\alpha$ -helices into SDS micelles, while the N-terminal  $A\beta$  segment remains unstructured outside the micelle surface.<sup>19,125</sup> Because the critical micelle concentration for SDS is 8.2 mM in water at 25 °C,<sup>152</sup> micelles clearly formed under the experimental conditions. With approximately 62–65 SDS molecules per micelle,<sup>156</sup> 50 mM SDS yields a micelle concentration slightly below 1 mM, i.e., much higher than the concentration of  $A\beta$  peptides. This means that each micelle will generally contain no more than one  $A\beta$  peptide, which effectively prevents  $A\beta$  aggregation and ensures that uranyl interactions are with monomeric  $A\beta$  peptides. The high SDS concentration used to obtain this condition, i.e., 50 mM, does not pose a problem in the current experiments. Even though 50 mM SDS would efficiently denature most folded proteins, such denaturing effects are not relevant for small intrinsically disordered peptides such as  $A\beta$  (in monomeric form).

**5.6. Fluorescence Measurements of Dityrosine Formation.** Fluorescence emission spectra between 330 and 480 nm (excitation at 315 nm) were recorded at room temperature with a Jobin Yvon Horiba Fluorolog 3 fluorescence spectrometer (Longjumeau, France) for two samples of 10  $\mu$ M  $A\beta_{40}$  peptide in 20 mM MES buffer, pH 7.3. One sample contained 100  $\mu$ M uranyl acetate to investigate the possible effects of uranyl ions on dityrosine formation. The control sample contained 100  $\mu$ M of the chelator EDTA to remove any free metal ions. All measurements were conducted in triplicate using a quartz cuvette with a 4 mm path length and containing a 0.7 mL liquid sample. Spectra were recorded after 0 and 24 h of incubation,

during which the samples were kept at room temperature without agitation or other treatment.

**5.7. Nuclear Magnetic Resonance Spectroscopy.** NMR spectroscopy experiments were conducted on a Bruker Avance spectrometer operating at 500 MHz and being equipped with a cryoprobe for increased sensitivity. Uranyl acetate was titrated to 92  $\mu\text{M}$  monomeric  $^{15}\text{N}$ -labeled  $A\beta_{40}$  peptides in 20 mM MES buffer (90/10  $\text{H}_2\text{O}/\text{D}_2\text{O}$ ) at either pH 7.3 or pH 5.1 at 5  $^\circ\text{C}$ . Two-dimensional  $^1\text{H}$ ,  $^{15}\text{N}$ -HSQC (heteronuclear single quantum coherence) NMR spectra were recorded during the titrations using settings with 128 t1 increments, 24 scans, and a 1 s recycle delay. The spectra were then processed and evaluated in the Topspin software (v. 3.2) using already published assignments for HSQC cross-peaks of  $A\beta_{40}$  in buffer at neutral pH<sup>157–159</sup> or at acidic pH.<sup>119</sup>

**5.8. Binding Affinity Measurements via Tyrosine Fluorescence Quenching.** The binding affinities between uranyl ions and  $A\beta_{40}$  peptides were evaluated via the quenching effect of uranyl on the intrinsic fluorescence of Tyr10, the only natural fluorophore in the wt  $A\beta$  peptide. Fluorescence measurements were conducted on a Jobin Yvon Horiba Fluorolog 3 fluorescence spectrophotometer (Longjumeau, France) using a quartz cuvette with a 4 mm path length. The fluorescence emission intensity of samples containing 20  $\mu\text{M}$   $A\beta$  peptides in 20 mM MES buffer, at either pH 7.3 or pH 5.5 and without or with 50 mM SDS detergent present, was measured at 305 nm (excitation wavelength 276 nm) at 20  $^\circ\text{C}$ . Aliquots of uranyl acetate (stock concentrations of 1, 2, and 10 mM) were titrated to the samples, and the Tyr10 fluorescence intensity was plotted against the concentration of  $\text{UO}_2^{2+}$  ions. Apparent dissociation constants ( $K_D^{\text{APP}}$ ) were determined by fitting the plots to eq 2

$$I = I_0 + \frac{I_\infty - I_0}{2 \cdot [\text{Ab}]} \cdot \left\{ (K_D + [\text{U}] + [\text{Ab}]) - \sqrt{(K_D + [\text{U}] + [\text{Ab}]^2 - 4 \cdot [\text{U}] \cdot [\text{Ab}])} \right\} \quad (2)$$

where  $I_0$  is the initial fluorescence intensity with no added  $\text{UO}_2^{2+}$  ions,  $I_\infty$  is the steady-state intensity at the end of the titration,  $[\text{Ab}]$  is the protein concentration, and  $[\text{U}]$  is the concentration of added  $\text{UO}_2^{2+}$  ions.<sup>121,160</sup>

**5.9. Blue Native Polyacrylamide Gel Electrophoresis.** Homogeneous solutions of oligomers of 80–100  $\mu\text{M}$   $A\beta_{42}$  peptides<sup>132</sup> prepared (as described in Section 5.2) in the presence of different concentrations of uranyl acetate (0–1000  $\mu\text{M}$ ) were analyzed with BN-PAGE using the Invitrogen system (Thermo Fisher Scientific, USA). Thus, 4–16% Bis–Tris Novex gels (Thermo Fisher Scientific, USA) were loaded with 10  $\mu\text{L}$  samples containing  $A\beta_{42}$  oligomer solutions alongside the Amersham high MW calibration kit for native electrophoresis (GE Healthcare, USA). The gels were run at 4  $^\circ\text{C}$  using the electrophoresis system according to the Invitrogen instructions (Thermo Fisher Scientific, USA) and then stained with the Pierce Silver Staining Kit according to the manufacturer's instructions (Thermo Fisher Scientific, USA). BN-PAGE was chosen for analysis instead of SDS–PAGE to avoid disruption of the SDS-stabilized and non-cross-linked  $A\beta_{42}$  oligomers by the high (>1%) SDS concentrations used in SDS–PAGE sample buffers.<sup>161</sup>

**5.10. Infrared Spectroscopy.** FTIR spectra of the SDS-stabilized  $A\beta_{42}$  oligomers (prepared as described in Section 5.2) were recorded in transmission mode on a Tensor 37 FTIR spectrometer (Bruker Optics, Germany) equipped with a sample shutter and a liquid nitrogen-cooled MCT detector. The unit was continuously purged with dry air during the measurements. 8–10  $\mu\text{L}$  of the 80–100  $\mu\text{M}$   $A\beta_{42}$  oligomer samples, prepared (as described in Section 5.2) with different concentrations of uranyl acetate (0–1000  $\mu\text{M}$ ), was put between two flat  $\text{CaF}_2$  disks separated by a 50  $\mu\text{m}$  plastic spacer covered with vacuum grease at the periphery. The assembled IR cuvette was mounted into the sample position of a sample shuttle inside the instrument's sample chamber, while a metal grid (used as the background) was positioned in the reference holder. The sample shuttle was used to measure the sample and reference spectra without opening the chamber. The samples were allowed to sit for at least 15 min after closing the chamber lid to avoid interference from water

vapor. FTIR spectra were recorded at room temperature in the 1900–800  $\text{cm}^{-1}$  range, with 300 scans for both background and sample spectra, using a 6 mm aperture and at a resolution of 2  $\text{cm}^{-1}$ . The light intensities above 2200  $\text{cm}^{-1}$  and below 1500  $\text{cm}^{-1}$  were blocked with a germanium filter and a cellulose membrane, respectively.<sup>162</sup> The spectra were analyzed and plotted with the OPUS 5.5 software, and second derivatives were calculated with a 17  $\text{cm}^{-1}$  smoothing range.

# Curriculum vitae

## Personal data

Name: Elina Berntsson  
Date of birth: 29.03.1993  
Place of birth: Stockholm, Sweden  
Citizenship: Swedish

## Contact data

E-mail: [elinaberntsson@gmail.com](mailto:elinaberntsson@gmail.com) ; [ebernt@taltech.ee](mailto:ebernt@taltech.ee)

## Education

2020–2025 Tallinn University of Technology, Estonia, PhD Student  
2018–2019 Uppsala University, Sweden, MSC  
2015–2018 Uppsala University, Sweden, BSC  
2008–2011 High school

## Language competence

Swedish Native  
English Fluent

## Professional employment

2019–2020 Research Traineeship, Stockholm University, Sweden  
2018–2018 Laboratory Assistant, Karolinska Institute, Sweden

## List of publications

**Berntsson, E.**, Sardis, M., Noormägi, A., Jarvet, J., Roos, P. M., Tõugu, V., Gräslund, A., Palumaa, P., & Wärmländer, S. (2022). Mercury Ion Binding to Apolipoprotein E Variants ApoE2, ApoE3, and ApoE4: Similar Binding Affinities but Different Structure Induction Effects. *ACS Omega*, 7(33), 28924-28931.

**Berntsson, E.**, Vosough, F., Svantesson, T., Pansieri, J., Iashchishyn, I. A., Ostojic, L., Dong, X., Paul, S., Jarvet, J., Roos, P. M., Barth, A., Morozova-Roche, L. A., Gräslund, A., & Wärmländer, S. (2023). Residue-specific binding of Ni(II) ions influences the structure and aggregation of amyloid beta (Abeta) peptides. *Scientific Reports*, 13(1), 3341.

Lakela, A., **Berntsson, E.**, Jarvet, J., Gräslund, A., Wärmländer, S. (2024). Secondary structures of human calcitonin at different temperatures and in different membrane-mimicking environments, characterized by circular dichroism (CD) spectroscopy. *Accepted for publication in ACS Omega*.

Lakela, A., **Berntsson, E.**, Vosough, F., Jarvet, J., Paul, S., Barth, A., Gräslund, A., Roos, P., Wärmländer, S. (2024). Molecular interactions, structural effects, and binding affinities between silver ions (Ag<sup>+</sup>) and amyloid beta (A $\beta$ ) peptides. *Accepted for publication in Scientific Reports*.

## Elulookirjeldus

### Isikuandmed

Nimi: Elina Bertsson  
Sünniaeg: 29.03.1993  
Sünnikoht: Stockholm, Rootsi  
Kodakondsus: Rootsi

### Kontaktandmed

E-post: [elina.bertsson@dbb.su.se](mailto:elina.bertsson@dbb.su.se) ; [ebernt@taltech.ee](mailto:ebernt@taltech.ee)

### Hariduskäik

2020–2025 Tallinna Tehnikaülikool, PhD  
2018–2019 Uppsala Ülikool, MSC  
2015–2018 Uppsala Ülikool, BSC  
2008–2011 Keskkharidus

### Keelteoskus

Rootsi keel emakeel  
Inglise keel kõrgtase

### Teenistuskäik

2019–2020 Praktikant, Stockholmi Ülikool, Rootsi  
2018–2018 Laborant, Karolinska instituut, Rootsi

### Publikatsioonid
