

THESIS ON CHEMISTRY AND CHEMICAL ENGINEERING G20

**Abatement of CO₂ emissions in
Estonian oil shale-based power
production**

MAI UIBU

TALLINN UNIVERSITY OF TECHNOLOGY
Faculty of Chemical and Materials Technology
Laboratory of Inorganic Materials

Dissertation was accepted for the defence of the degree of Doctor of Philosophy (Chemical and Materials Technology) on October 6, 2008.

Supervisor: Leading Research Scientist Rein Kuusik, Laboratory of Inorganic Materials, Tallinn University of Technology

Co-Supervisor: Professor Andres Triikkel, Tallinn University of Technology

Opponents: Professor Ron Zevenhoven, Åbo Akademi University
Professor Rein Munter, Tallinn University of Technology

Defence of the thesis:

December 16, 2008, at 11.00

Lecture hall: VII-131

Tallinn University of Technology, Ehitajate tee 5, Tallinn

Declaration: Hereby I declare that this doctoral thesis, my original investigation and achievement, submitted for the doctoral degree at Tallinn University of Technology has not been submitted for any academic degree.

Author's own contribution

The contribution by the author to the papers included is as follows:

- I Interpretation of the results, minor contribution
- II Specific surface area measurements, interpretation of the results, major role in writing
- III Planning and conducting the experiments, interpretation of the results, major role in writing
- IV Participating in planning and conducting the experiments, interpretation of the results, major role in writing
- V Planning and conducting the experiments, interpretation of the results, major role in writing

INTRODUCTION

Human activities are generally considered responsible for the so-called greenhouse effect and the consequent climate changes [1]. The concentration of CO₂ in the atmosphere has increased rapidly from 280 ppm since the beginning of industrialization and extensive using of fossil fuels reaching 384 ppm in 2007, an annual growth rate being almost 2 ppm since the year 2000. This increase has been considered being a major factor behind the raise of the earth's temperature. To avoid the risk of global warming and climate change, the anthropogenic CO₂ emissions into the atmosphere should be considerably reduced.

The heat and power production, which is still based mainly on fossil fuels, is a leading contributor to the emission of the greenhouse gas CO₂. Its content in the atmosphere could be stabilized by either increasing the natural/biological binding of CO₂ from the atmosphere or reducing the CO₂ emissions. The latter could be achieved (a) by reducing the fossil energy sources in energy production (e.g. renewable energy, nuclear power, lower C/H ratio), (b) by improving the energy efficiency and energy conversion technologies or (c) by more intensive implementation of the carbon capture and storage (CCS) technologies [1].

In the Republic of Estonia, local low-grade carbonaceous fuel, Estonian oil shale, is used as a primary energy source. Estonian oil shale differs from other fossil fuels in its high proportion of mineral CO₂ in the form of limestone and dolomite, and a higher specific carbon emission factor: 29.1 t C/TJ against 25.8 and 15.2 t C/T in coal and natural gas, respectively. In Estonia, the power sector is the largest CO₂ emitter and is also a producer of huge amounts of waste ash (45–47% of oil shale burnt, dry mass basis).

According to the Kyoto Protocol, during the period of 2008-2013 Estonia is obligated to reduce the emissions of air-polluting greenhouse gases from its territory by 8% as compared to year 1990 level. To reduce the CO₂ emissions several mitigation strategies, projections, legal acts and programs (in particular Estonian National Environmental Strategy, and GHG Emission Reduction Programme for 2003–2012 [2]) have been elaborated and enforced in Estonia. The main options are improving energy efficiency, shift to low-carbon fuels and wider use of renewable energy sources. As the renewable options are currently far from covering Estonia's energy demand, even the use of nuclear power has been under discussion. In order to continue using oil shale as a primary energy source, its environmental impact including CO₂ emission should be diminished.

Acknowledgements

I wish to thank my supervisors Rein Kuusik and Andres Trikkel as well as the rest of my colleagues at the Laboratory of Inorganic Materials for all the help during the research. The consultation of Dr. Valdek Mikli, Dr. Olga Volobujeva and Prof. Kalle Kirsimäe is highly appreciated. Financial support from the Nordic Energy Research, UTTP Doctoral School and SC Narva Elektriijaamad is acknowledged. Special thanks go to my loved ones for their patience and support.

LIST OF ABBREVIATIONS

AAS	Atomic absorption spectrophotometry
AOD	Argon-oxygen decarburisation
APC	Air pollution control
BD _{CaO}	CaO-binding degree
BD _{CO₂}	CO ₂ -binding degree
BD _{CO₂} *	CO ₂ -binding degree calculated on free CaO basis
BET	Absorption theory by S. Brunauer, P. H. Emmet and E. Teller
CCS	Carbon dioxide capture and storage
CFBC	Circulating fluidized-bed combustion
CO _{2max}	Maximal CO ₂ -binding capacity
CRW	Carbonated recirculation water
DW	Distilled water
EDX	Energy dispersive X-ray analysis
EDTA	Ethylenediaminetetraacetic acid
FG	Flue gas
GGBS	Ground granulated blast furnace slag
IGCC	Integrated gasification combined cycle
IR	Indissoluble residue in <i>aqua regia</i>
k _{CO₂}	Decomposition rate of carbonate part of oil shale
<i>k</i>	Mole ratio of CO ₂ ^(g) contacted with the pulp and free CaO present in the initial pulp
K _s	Solubility product
LOI	Loss on ignition
MSWI	Municipal solid waste incineration
N _{CO₂}	Degree of carbonation
PCC	Precipitating calcium carbonate
PF	Pulverized firing
RW	Recirculation water
SEM	Scanning electron microscopy
SSA	Specific surface area
XRD	X-ray diffraction
α	Conversion rate of dissolved CO ₂
ΔG_T	Gibbs energy change (kJ/mol)
ΔH	Reaction enthalpy (kJ/mol)
Ash types:	
BA	Bottom ash
FA	Filter ash
CA	Cyclone ash
ECO	Economizer ash
ESPA	Electrostatic precipitator ash
INT	Intrex ash
PHA	Air preheater ash
SHA	Superheater ash

1. LITERATURE OVERVIEW

1.1. CO₂ capture and storage

Carbon dioxide (CO₂) capture and storage is a process consisting of the separation of CO₂ from industrial and energy-related sources, transport to a storage location and a long-term isolation from the atmosphere [1].

The capture step involves separating CO₂ from other gaseous products. For the energy sector, there are three main approaches for capturing CO₂ generated from fossil fuel: *post-combustion*, *pre-combustion* and *oxy-fuel* combustion systems (Fig. 1). *Post-combustion* systems separate CO₂ from a flue gas stream. These systems typically use a liquid amine-based solvent to capture the small fraction of CO₂ (3–15% vol.) present in a flue gas stream, whose main constituent is nitrogen [3]. *Pre-combustion* systems remove CO₂ prior to combustion, including gasification of the primary fuel, water gas shift and CO₂ separation. Although the initial fuel conversion steps are elaborate and costly, the high concentrations of CO₂ produced by the shift reactor (15–60% vol.) and the high pressures are favorable for CO₂ separation. Pre-combustion is most suitable for the power plants that employ integrated gasification combined cycle (IGCC) technology. *Oxy-fuel combustion* systems use oxygen from air-separation unit for combustion of the primary fuel to produce flue gas that mainly consists of water vapour and CO₂. The water vapour is then removed by cooling and compressing [1].

Figure 1. CO₂ capture pathways [4]

However, CO₂-capture systems require significant amounts of energy to operate. This reduces the plant efficiency, because the power plants require more fuel (ca

11–40%) to generate each kilowatt-hour of electricity produced. Net costs of the captured CO₂ for a coal- or gas-fired power plant are 15–75 US\$/tCO₂ [1].

In most cases, after drying and compression the captured CO₂ must be transported to the storage site, since appropriate storage sites are rarely located near the CO₂ source. Transportation by pipelines (under the pressure above 80 bar) is the most common and mature technology. For long-distance transport, CO₂ might also be transported as a liquid by ship (under the 7-bar pressure). The cost of the pipeline transport depends on the flow rate, terrain, offshore/onshore transportation and distance, and is typically 1–8 US\$/tCO₂ for a nominal distance of 250 km [1].

In order for CCS to be a useful option for reducing the CO₂ emission, the captured CO₂ has to be stored isolated from the atmosphere for a long period of time (thousands of years) [1]. The only mature technology currently available is CO₂ storing into geological formations, including oil and gas reservoirs, deep saline formations, and unminable coal beds. In the case of geological storage, the estimated CO₂-storage capacity ranges between 2,000–10,000 Gt CO₂ [1]. Several industrial-scale projects (such as the Sleipner project in the North Sea, the Weyburn project in Canada [5] and In Salah project in Algeria) have been storing CO₂ in geological formations. The estimated cost of the CO₂ storage in saline formations and depleted oil and gas fields is 0.5–8 US\$/tCO₂ injected plus 0.1–0.3 US\$/tCO₂ for monitoring [1].

A potential CO₂-storage option is to inject CO₂ directly into the deep ocean (at the depths greater than 1,000 m, where most of the CO₂ would be isolated from the atmosphere for centuries). Stabilizing the atmospheric CO₂ concentrations between 350 and 1,000 ppm would imply that 2,000–12,000 Gt CO₂ would eventually end up in the ocean on the time scale of thousands of years. The latter figures also represent the upper limit for the capacity of the active CO₂ injection. The cost for CO₂ injection into the ocean at 3,000-m depth has been estimated to be 6–31 US\$/tCO₂. However, little is known about the effect of actively injecting CO₂ on the ocean environment [1]. This option is receiving less and less attention.

Another option for CO₂ storage is the fixation of CO₂ in the form of inorganic carbonates, also known as mineral carbonation or mineral sequestration. Carbonation of alkaline minerals mimics the natural rock weathering and involves the permanent storage of CO₂ as the thermodynamically stable form of calcium and magnesium carbonates [1]. Moreover, magnesium and calcium silicate deposits are sufficiently abundant to fix the CO₂ that could be produced from the combustion of all fossil fuels sources [1, 5]. However, the technology CO₂ sequestration through mineral carbonation has not yet been developed at the full scale due to cost limitations: a power plant equipped with a full CCS system with mineral carbonation would require much more (from 60 to 180%) energy than power plant without CCS. Also, significant environmental impacts of the large-scale mineral carbonation would be a consequence of the required mining (1.6–3.7 tons of silicate rock to store 1 ton of CO₂) and disposal of resulting products that have little or no practical use [1]. It has been estimated that the sequestration costs of current

mineral carbonation (78–310 US\$/tCO₂) are high relative to the costs of geological capture and storage options [6].

All in all, even though rules and regulations have been formulated and various technologies suggested, the major break-through in reducing the global CO₂ emissions is yet to come.

1.2. CO₂ sequestration by mineral carbonation

Mineral carbonation was first mentioned as a concept for CO₂ abatement by Seifritz in 1990 [7] and developed by Dunsmore [8] and Lackner [9-12]. Since then, research on the mineral carbonation has divided into several different CO₂ binding approaches (Fig. 2) - mainly direct and indirect carbonation [13, 14].

At first, only natural Ca- and Mg-rich minerals such as olivine, serpentine, wollastonite and talc, which are wide-spread and inexpensive, were considered as raw materials [15-18]. Since 1998, the carbonation of industrial wastes such as ashes [19], air pollution control (APC) equipment residues [19, 20] steel slag [21-24] and waste cement [25], which contain considerable amount of Ca or Mg, has also been studied. Although the potential CO₂-storage capacity of such waste materials is limited (the amounts of material that may be carbonated are just too small [26]), the possibility of binding CO₂ and simultaneously lowering the hazardous effect of waste materials gives this approach an extra value.

Figure 2. Main carbonation processes [13, 14]

1.2.1. Direct carbonation of Ca- and Mg-rich minerals and waste residues

Direct carbonation is the simplest approach to the mineral carbonation. The main idea is that the suitable feedstock (natural mineral or solid wastes) is carbonated in one stage. In the case of aqueous process, both the extraction of metals from the feedstock and the subsequent reaction with the dissolved carbon dioxide to form carbonates take place in the same reactor [14].

1.2.1.1. Direct gas–solid reaction

A direct gas–solid reaction of natural minerals, requiring elevated temperatures and pressures (500°C, 340 bar) appears unviable for industrial processes because of very slow reaction rates and thermodynamic limitations [10, 27]. Gas–solid carbonation of MSWI ashes and APC residues gave more promising results [20, 26, 28] in the environment of elevated temperatures (200–500°C) or high pressures (17 bar).

1.2.1.2. Direct aqueous carbonation of natural Ca- and Mg-rich minerals

In the aqueous process, carbonation occurs in the three-phase system (gas–solid–water medium), which considerably increases the reaction rate as compared to gas–solid route.

Direct aqueous carbonation of minerals is a process, in which a slurry of water mixed with pre-treated Mg- or Ca-rich silicates is reacted with carbon dioxide to produce carbonates (Eqs. (1–3)). Carbon dioxide is dissolved in water to form carbonic acid, which dissociates to hydrogen cations and bicarbonate anions. The hydrogen cations react with the mineral, liberating magnesium cations, which, in turn react with bicarbonate to form the solid carbonate [29]. Several silicate minerals achieved carbonation reaction rates sufficient for industrial application at elevated temperatures and pressures [30] and/or in the presence of additives (Table 1), while being relatively inactive at ambient temperature and under sub-critical CO₂ pressures (below 74 bar).

Table 1: Optimum carbonation conditions and extent of carbonation

Mineral or residue	T, °C	P _{CO₂} , atm	Carrier solution	Duration	Extent of carbonation	Ref.
Olivine	185	150	0.64M NaHCO ₃ , 1M NaCl	1 h	49.5%	[31]
Serpentine	155	115	0.64M NaHCO ₃ , 1M NaCl	1 h.	75.5%	[31]
Wollastonite	100	40	Distilled water	1 h	81.8%	[31]
Wollastonite	200	20	Distilled water	15 min	70%	[32]
Steel slag	100	19	Distilled water	30 min	74%	[23]

To speed up the kinetics of the direct aqueous carbonation process, various physical and chemical pre-treatment methods [33], as well as mechanical procedures [34] and heat-activation of the minerals [35] with the purpose to enlarge the reaction surface have been studied. Intensified mixing that causes high-energy particle–particle interactions can be used to remove the rate-limiting SiO₂ and carbonate layers to enhance the reaction rate [17]. Certainly, enhancing the reactivity of minerals requires extra energy or chemical additives and thereby increases the costs.

Acids (HCl, acetic acid and citric acid [11]) and complexing agents, while enhancing the dissolution of minerals, can complicate the carbonation/precipitation

step by lowering the pH too much for carbonate precipitation to occur or by the formation of too strong complexes [13]. To execute both reactions in one step a careful optimization is needed.

1.2.1.3. Direct aqueous carbonation of waste residues

One way of bypassing some of the draw-backs of the accelerated carbonation of primary alkaline earth minerals is to use the alkaline waste residues from thermal processes or from construction and demolition activities as a feedstock. As these materials are often associated with CO₂ point source emissions and tend to be chemically more unstable than geologically derived minerals [22], they require a lower degree of pre-treatment and less energy-intensive operating conditions to enhance carbonation yields [22, 36]. Furthermore, after stabilization by the accelerated carbonation, the leaching behavior of the alkaline waste materials such as municipal solid waste incinerator ashes [26, 37, 38], steel slag [22] and APC incinerator residues [19, 28, 39] is improved, allowing for use in civil engineering applications or for safer final disposal to landfill. Accelerated carbonation can be used to stabilize many of the industrial residue streams produced from coal- and oil shale-fired power plants, including pulverized fly ash (PFA) [40], fluidized bed combustion (FBC) [41] and circulating fluidized-bed combustion (CFBC) ashes [42, 43] (Table 2). Beside the effects of carbonation on the mechanical properties of cement-based materials [44], recently the research has also focused on the accelerated carbonation treatment to promote the stabilization degree and to improve the leaching behavior of the treated material [25].

Table 2: Composition of some calcium silicate-containing waste residues suitable for accelerated carbonation (weight, %)

Sample	CaO	SiO ₂	MgO	Al ₂ O ₃	Fe ₂ O ₃	Ref.
APC	65.04	20.71	1.03	4.83	2.77	[19]

Wollastonite	44.50	52.20	0.54	1.48	0.30	[24]

The accelerated carbonation of alkaline solid waste has been up to now primarily investigated through the direct aqueous route [6, 22, 37, 46]. The carbonation of residues does not generally require the extraction of alkaline metals from the solid matrix, since the main reactive species are Ca-containing silicates, oxides and

hydroxides. These minerals behave differently from those containing Mg, as hydration, solvation and carbonation occur under the same operation conditions in a one-stage operation [19].

Accelerated carbonation of steel slag

The accelerated carbonation of waste materials of low solubility in which Ca is generally bound as silicate (steel slag) is in most cases carried out in a water slurry phase ($L/S > 1$ w/w) [21, 22, 47]. Depending on residue composition, different operational parameters have been identified [23, 25, 48] and CO_2 uptake in materials with high content of alkaline oxide silicates, such as steel slag, has shown to be influenced by operational parameters (pressure, temperature, particle size distribution) similarly to carbonation of minerals such as wollastonite; however, optimum operational conditions for the processing of residues were found to be less energy demanding ($T = 100^\circ\text{C}$, $p_{\text{CO}_2} = 19$ bar, Table 1). The carbonation reaction was found to occur in two steps; 1) leaching of calcium from steel slag particles into solution; 2) precipitation of calcite on the surface of particles. The first step and, more in particular, the diffusion of calcium through the solid matrix toward the surface appeared to be rate-limiting step. The Ca diffusion was found to be hindered by the formation of a CaCO_3 coating and Ca-depleted silicate zone during the carbonation process [23].

Accelerated carbonation of MSWI bottom ash

MSWI BA represents 80% of the incinerator residue produced and is classified as a non-hazardous waste (European Waste Catalogue) consisting mainly of aluminosilicate phases and certain amounts of metallic components (8%), including Cr, Ni, Cu, Zn, Ba, Pb, Cd, As, Ti, Mn and Hg. As Ca and Mg contents are typically not high enough for significant CO_2 sequestration, the application of the accelerated carbonation is therefore applied with the aim to attain a chemically stable structure with improved leaching behavior [19, 46].

The carbonation of BA has been investigated to track the mineralogical changes similar to those resulting from natural weathering and to induce a related reduction in trace metal mobility [37, 38, 49]. Recent studies have also focused on the principal carbonation mechanisms and controlling operating parameters, such as temperature, CO_2 partial pressure, water proportion, residence time, as well as particle size [26, 46].

Table 3 gives a summary of the operating conditions for the accelerated carbonation: the water solid ratio is either low-ranged (0.05–0.6 w/w), or indicates to slurry-phase conditions (5–20 w/w); the pressure varies from atmospheric to 17 bar, the temperature is between ambient and 50°C , the CO_2 percentage is 0.03–100% and residence times range from hours to weeks.

Due to the complex chemistry and mineralogy of the material, the mechanisms involved in the carbonation of BA are not yet well known. However, it is likely that more than one alkaline oxide-containing mineral (including Ca and Mg silicates) reacts with CO_2 in addition to calcium hydroxide. Most of the studies reported have considered a simplified carbonation of $\text{Ca}(\text{OH})_2$ via an aqueous route

[26, 50]. The rate-limiting steps of the carbonation reaction involve the dissolution of calcium from the solid matrix into the liquid phase and the diffusion of CO₂ into the pores. The kinetics of CO₂ uptake is generally characterized by two reaction steps: (1) an increase in the rate of CO₂ uptake with time, which is followed by (2) a decrease in the rate until an approximately constant value of CO₂ uptake is achieved [26, 37, 46]. The first reaction stage probably involves "faster" reacting minerals such as Ca(OH)₂, whereas the second stage may involve other, less reactive, minerals [23]. Therefore, the degree of carbonation should be calculated as the conversion of all Ca-reacting species found in feedstock to calcium carbonate.

Table 3: Conditions for accelerated carbonation of MSWI BA and APC residues

CO ₂ conc.	Pressure	Temperature	Duration	Water proportion	Ref.

Accelerated carbonation of APC residues

APC residues are typically a mixture of the fly ash, carbon and lime; they form as a result of the treatment process to clean the flue gases before they are released to the atmosphere. Due to the high lime content (typically pH>12), and high concentration of heavy metals, soluble salts and chlorinated compounds, APC residues are classified as a hazardous waste. High percentage of readily-active calcium hydroxides makes the carbonation of APC residues potentially suitable for the CO₂ sequestration purposes [20, 28, 46] and also decreases the pH value to the levels corresponding to minimum solubility and regulatory limits (pH<9.5) [25, 55]. Accelerated carbonation induces a mineralogical change in the APC residues: the conversion of hydroxides into carbonates results in a consequent lowering of pH that affects the leachability of many elements and enhances the acid-neutralization capacity of the material.

The mechanisms governing the APC carbonation are more straightforward than those of BA carbonation, since the reactive species are almost entirely composed of portlandite and CaClOH. In the case of APC residues the kinetics of CO₂ uptake shows the same trend as for BA, although with higher weight gains, which result from higher lime contents, and larger specific surface areas and microporosity [46].

Carbonation affects the leaching at three levels: it causes the decrease of porosity, the lowering of pH and transformation of hydroxides into carbonates. During the carbonation of APC residues via an aqueous route, the following parameters are of critical importance: water proportion (optimal value 0.2–0.3 w/w), particle size (optimal value 212 µm), temperature and CO₂ partial pressure. The CO₂-uptake potential of APC residues reaches 120 g CO₂ per kg APC residues [20, 55].

1.2.2. Indirect carbonation of Ca- and Mg-rich minerals and waste residues

In the case of indirect carbonation the reactive component (Ca or Mg) is first extracted from the feedstock (as oxide or hydroxide) in one step and then reacted with carbon dioxide to form carbonates as the next step.

1.2.2.1. Indirect gas–solid carbonation

The direct gas–solid carbonation of calcium/magnesium oxides/hydroxides proceeds much faster than the gas–solid carbonation of calcium/magnesium silicates [10]. On the other hand, magnesium/calcium oxides are rare in nature and have to be produced from calcium/magnesium silicates. As the carbonation of MgO is significantly slower than the carbonation of Mg(OH)₂ [56, 57], the direct gas–solid carbonation process should be divided into several steps: for example, the step of the extraction of magnesium oxide under atmospheric pressure followed by the steps of hydration and carbonation at elevated temperature (>500°C) and pressure (>20 bar) [56].

1.2.2.2. Indirect aqueous carbonation of natural Ca- and Mg-rich minerals

The addition of acids and complexing agents in a single-step aqueous carbonation process causes a need for balancing the process conditions between an optimum for the dissolution and for the precipitation step. Therefore, it might be advantageous to perform the aqueous route in two steps [34] in a so-called pH-swing process. The pH-swing process first step, which takes place at low pH, is to dissolve the Mg from serpentine (at 70°C, under the ambient pressure, using aqueous solution of 1% vol. orthophosphatic acid, 0.9% wt. oxalic acid and 0.1 % wt. EDTA [34]) and the second step, which proceeds at higher pH (pH~9.5 by adding NH₄OH), is to form carbonates. Precipitated solid SiO₂ and iron oxide were removed by filtration before carbonation step. The conditions required to obtain a significant conversion (42–65%) are much milder compared to typical direct aqueous carbonation (185°C and 150 atm). A similar process for leaching Ca and Mg from silicate minerals using sulphuric acid has also been proposed [33] for subsequent carbonation.

Another aqueous carbonation route uses acetic acid for the extraction of Ca^{2+} -ions from a calcium rich feedstock [58]. After separation of the solid SiO_2 , the gaseous CO_2 is led into the solution to form CaCO_3 . The best conversion achieved for wollastonite was about 20% in 60 min under total pressure of 30 bar.

To remove the passivating SiO_2 -rim, several in-situ physical activation methods such as intensive stirring [59], internal grinding by glass beads [34] and ultrasonic and acoustic treatment [60] have been studied.

Although numerous mineral carbonation routes consisting of multiple steps and using various additives (CH_3COOH [58], H_2SO_4 [33], HCl [10], NaOH [61]) have been suggested over the last decade, the drawbacks related to the recycling of the acid and other chemicals make the processes too expensive for industrial applications [62, 63].

1.2.2.3. Indirect aqueous carbonation of alkaline waste residues

The processes described in the last chapter could also be applied to carbonating industrial residues that are more easily carbonated [47]. Also, the expensive CO_2 sequestration by indirect carbonation might become economically feasible due to upgrading waste products into products of high commercial value, such as high-purity precipitated calcium carbonate (PCC) or magnesium carbonate [24, 47, 62, 64, 65].

The feasibility of producing CaCO_3 from waste cement [64], paper bottom ash [66] and steel slag [66] has been studied. The process is as follows: extracting Ca from waste material using high CO_2 pressures as a first step, followed by precipitation of calcium carbonate from the extracted solution at lower CO_2 pressures as a second step [64]. Production of CaCO_3 using this process would cost 136 US\$/t CaCO_3 for desulphurization purposes and 322 US\$/t for obtaining a high-purity CaCO_3 .

1.3. Basics of aqueous carbonation of lime-based systems

Industrial wastes such as APC residues and ashes from solid fuel combustion often contain a considerable proportion of free lime (20–30%) as the main CO_2 -binding compound. Therefore, the mechanism and factors influencing the processes of slaking, dissolution and carbonation of lime are also discussed here.

Industrial powdered calcite is usually produced by bubbling CO_2 through an aqueous slurry of slaked lime (Eq. (4)). The industrial process involves the following steps: (1) calcination of limestone (natural CaCO_3 rocks) to produce quicklime (CaO) and CO_2 ; (2) a slaking process, in which the quicklime is transformed into slaked lime slurry by addition of H_2O ; and finally (3) the CaCO_3 precipitation reaction, in which the by-product CO_2 mixed with air is bubbled through the $\text{Ca}(\text{OH})_2$ suspension [67, 68]. CaCO_3 precipitation involves four steps: dissolution of $\text{Ca}(\text{OH})_2$, CO_2 absorption into the lime solution, chemical reaction and crystal growth [68].

1.3.1. Factors affecting lime slaking and dissolution of Ca(OH)₂

The reaction of lime and water (e. g. lime slaking) is strongly exothermic. When exposed to water, regardless of its form (liquid, steam, vapor or ice), quicklime exhibits a strong affinity for moisture and adsorbs it into pores. As the water penetrates into the surface pores, heat of hydration is being released. This in turn exerts great internal expansive forces in the lime particle and causes it to fracture, shatter, and then disintegrate into microparticles, in the form of either a crystalline dust or a colloidal suspension, depending on the proportion of water [69].

The slaking reaction can be considered to proceed in three steps: step 1, the conversion of calcium oxide to calcium hydroxide (Eq. (5)) is followed by step 2, the dissolution of calcium hydroxide to give calcium ions and hydroxide ions on the surface (Eq. (6)) and next by step 3, the diffusion of the calcium ions and hydroxide ions into the bulk of the solution (Eq. (7)) [67, 68]. The rate of hydration is influenced by the porosity, the amount of impurities (for example MgO retards reaction rate, while slag forming from silica, alumina or iron clogs the pores), the calcium oxide particle size, the time and temperature of limestone calcination, the amount of water added and agitation [69, 70]. As a function of the stirring efficiency Ca(OH)₂ dissolution can be either chemically or diffusion controlled: under moderate agitation (<300 rpm) the overall rate is controlled by diffusion of Ca²⁺ and OH⁻ ions from the reacting surface, and under more vigorous agitation (>300 rpm) the dissolution of Ca(OH)₂ at the surface controls the rate [67, 70, 71].

As even minute amounts of extraneous substances present in water affect the extent and rate of lime solubility in water, the water quality can be critically important in lime slaking [69, 70, 72, 73]. In the presence of Ca²⁺- and OH⁻-ions the slaking rate drops because the reaction is also controlled by the diffusion of calcium hydroxide away from the surface [70]. Carbonate ions and sulfate ions in the slaking water can form insoluble layers of both CaCO₃ and CaSO₄, which partially or completely coat the surface and thereby prevent the further dissolution or slow it down [73]. The recycled wastewaters, such as SO₂ scrubbing water that contains over 500 mg/l of sulfite, sulfate and bisulfate ions, retard the slaking rate by vitiating the lime reactivity, reducing the hydrate yield and creating coarse to granular particles that sediment rapidly [69]. However, wastewaters from SO₂ scrubbing can be employed to dilute a the slaked lime slurry without deleterious consequences [69].

When calcium oxide is immersed in a carbonate-containing aqueous solution, two reactions take place: the usual lime-slaking reaction and the formation of calcium carbonate on the lime surface. The effect of CaCO₃ layer on CaO is to hinder both the lime slaking reaction and the formation of further calcium carbonate. At carbonate concentrations 0.01–0.05 M calcium carbonate forms a coherent film on the calcium hydroxide, thus denying water access to surface and

preventing the further dissolution of the slaked lime. At higher carbonate concentrations ($>0.05\text{M}$) the slaking rate starts increasing again due to the direct carbonate attack to the lime surface. This leads to formation of a heterogeneous calcium carbonate/calcium hydroxide surface layer, which is relatively permeable to diffusing species [72].

1.3.2. CO_2 absorption into the lime solution

Carbon dioxide is slightly soluble in pure water, depending strongly on the temperature and partial pressure. At pressures up to 5 atm, the solubility follows Henry's law $[\text{CO}_2^{\text{aq}}] = K_{\text{H}} \cdot p_{\text{CO}_2} = 3.65 \cdot 10^{-2} \cdot p_{\text{CO}_2}$ [74]. CO_2 absorption into the lime solution is favored by both presence of solid particles of $\text{Ca}(\text{OH})_2$ and the chemical reaction (Eq. (4)). After CO_2 is absorbed to water it hydrates to form $\text{CO}_2(\text{aq})$ or carbonic acid (H_2CO_3) (Eq. (8)) for the most part [68]. Dissolution of CO_2 in water depends on the pH, because the formed H_2CO_3 ($\text{CO}_2 \cdot \text{H}_2\text{O}$) dissociates to HCO_3^- (Eq. (9)) and CO_3^{2-} (Eq. (10)) and, accordingly, the overall concentration of dissolved carbon increases together with the amount of HCO_3^- and CO_3^{2-} -ions formed. The fractional amounts of carbonate species present in solution depending on its pH are presented in Fig 3.

Figure 3. Dependence of the fractional amounts of all carbonate species α as a function of the solution pH [75]

1.3.3. Chemical reaction of calcite precipitation and crystal growth

Calcite precipitation in the system $\text{Ca}(\text{OH})_2\text{-H}_2\text{O-CO}_2$ starts with the dissolution of $\text{Ca}(\text{OH})_2$ and CO_2 that increases the concentration of charged dissolved species (ions) such as Ca^{2+} , OH^- , HCO_3^- , CO_3^{2-} , CaOH^+ , CaHCO_3^+ and uncharged CaCO_3^0 [67]. CaCO_3 precipitation leads to a decrease in these concentrations. In the initial ascending zone, the dissolution rates of $\text{Ca}(\text{OH})_2$ and CO_2 are higher than the

precipitation rate of CaCO₃. Maintaining the flow rate of CO₂-containing gas constant, this process leads to the accumulation of an excess of the dissolved Ca(OH)₂ in the growth medium [67].

The driving force for CaCO₃ precipitation is the supersaturation determined by the product of the ionic concentration of calcium and carbonate ions [68]. Along the batch carbonation process, monitoring of the electrical conductivity and/or pH is normally used as a tool to detect the end point of the reaction. The process of calcium carbonate precipitation by carbonation of slaked lime is a heterogeneous reaction maintained at nearly constant supersaturation. This is reflected generally in the constancy of the values of pH and Ca²⁺ concentration recorded against the time. After Ca(OH)₂ consumption, the supersaturation decreases until zero, indicating the end point of neutralization [76].

The reaction of calcite precipitation at high reactant concentration proceeds through the initial precipitation of a kinetically favored amorphous (am) hydrated form (Eq. (11)) [68].

Amorphous CaCO₃ has been described as consisting of little spherical shapes, whose diameter is less than 1 μm. Because of the higher solubility of the amorphous phase compared to the crystalline phase, the precursor tends to change into the more stable crystalline modification. Transformation from the amorphous to calcite requires a passage in solution (Eq. (12)). At high CO₂ pressures, the crystallization of amorphous CaCO₃ can partially cover the Ca(OH)₂ particles inhibiting its dissolution and becoming the primary limitation in increasing the rate of carbonation reaction [68].

Several factors including pH, supersaturation, temperature, type and concentration of impurities/additives play an important role in the crystal growth and aggregation phenomena. They affect the growth rates of different crystal faces and the surface electrical properties of calcite during its growth in aqueous suspensions [76].

1.4. Estonian oil shale based energy sector as major contributor of CO₂ emissions and waste ash

1.4.1. Greenhouse gas emissions in Estonia

The most significant greenhouse gas (GHG) in Estonia is carbon dioxide. It contributes 87.1% to the total national GHG emissions in CO₂ equivalent and is followed by methane, 9.1%, and nitrous oxide, 3.7% (based on the year 2005 data, [77]). In 2005, the total of GHGs emitted, measured in CO₂-equivalents, was 12,562.3 Gg. Mainly due to the re-structuring and reduction of the industrial production, by 2005 Estonia has reduced its GHG emissions by 52.6 % compared to 1990. Nevertheless, the Republic of Estonia is among the 16 largest emitters of

CO₂ per capita in the world (14.1 tons of CO₂ per capita). Energy-related activities are the major contributors to GHG emissions (Table 4): a total of 18,381 Gg of CO₂ equivalent was emitted from the energy sector in 2005 (Table 5). That is 89% of the total GHG emissions for that year [77].

The Republic of Estonia signed the Framework Convention on Climate Change at the United Nations Conference on Environment and Development held in Rio de Janeiro in June 1992. In 1994, Estonia ratified the UN FCCC and in 2002 the Kyoto Protocol. Under the Protocol, Estonia is obligated to reduce the emissions of air-polluting GHGs from its territory by 8% as compared with 1990 level during the period of 2008–2012 [77]. Several mitigation strategies, projections, legal acts and programs (including Estonian National Environmental Strategy and GHG Emission Reduction Programme for 2003–2012) have been elaborated and enforced in Estonia. The main goal is to improve the energy efficiency in both the energy sector and the industry, but also for demand side developments.

Table 4: GHG emissions in Estonia in 1990-2005 [77].

Sources/Sinks	CO ₂ equivalent (Gg)			
	1990	2000	2002	2005
Energy	38,834.33	17,180.55	17,293.64	18,381.51
Industrial processes	945.59	587.80	423.35	559.19
Agriculture	3124.40	1,172.20	1,090.92	1,187.00
Land use and forestry	-9,362.90	-8,799.53	-7488.28	-8,096.26
Waste	690.08	797.02	546.44	530.58
Total net emissions	34,231.5	10,938.04	11,866.07	12,562.02

A significant effect on the reduction of CO₂ emission has been achieved due to the introduction of an up-to-date combustion technology, the fluidized-bed combustion of oil shale, at the SC Narva Power Plant. Increasing the fractional amount of the natural gas in the primary energy consumption would decrease the CO₂ emissions because the natural gas is the least carbon-intensive fossil fuel. An important option for reducing the CO₂ emissions is a wider use of renewable energy sources. In Estonia, a biomass is the most essential renewable option, while the wind energy has a smaller importance and the small-scale hydropower minor significance [78].

Table 5: Emissions from fuel combustion in Estonia in 1990–2005 (Gg CO₂ eqv) [77].

	1990	2000	2002	2005

1.4.2. Waste flows from Estonian oil shale-based energy sector

Most of the Estonia's energy demand is satisfied by an oil shale; and approximately 67% of the CO₂ emissions come from its combustion. As a fuel, Estonian oil shale is characterized by a high ash content (45–50%), a moderate content of moisture (11–13%) and sulphur (1.4–1.8%), a low net caloric value (8–9 MJ/kg) and a high content of a volatile matter in the combustible part. The dry matter of Estonian oil shale is considered to consist of the three main parts: an organic part, a sandy-clay part and a carbonate part (Table 6). During the pulverized combustion of oil shale, CO₂ is not only formed as a burning product of organic carbon, but it is also formed as a product of decomposition of the fuel's mineral part (*i.e.* carbonates). This makes the carbon emission factor of oil shale relatively high, being 29.1 tC/TJ. The total quantity of carbon dioxide increases up to 25% in flue gases of oil shale combustion [77].

Historically, energy recovery from the oil shale was based on the pulverized firing (PF), which is characterized by low efficiency and high emissions. Recently, new circulating fluidized bed combustion (CFBC) technology has been installed by SC Narva Power Plant, where two units, each of 215 MW capacity are in operation since the beginning of 2005. Due to a lower rate of decomposition of carbonates present in the mineral matter of oil shale (0.6 in the case of CFBC, at operating temperatures 720–800°C and 0.97 in the case of PF at 1,250–1,400 °C), the reduction of CO₂ emissions per unit of energy reached 13–18%.

Table 6: Chemical composition of Estonian oil shale [79]

Organic part		Sandy-clay part		Carbonate part	
Component	%	Component	%	Component	%
C	77.45	SiO ₂	59.2	CaO	53.5
H	9.70	CaO	0.7	MgO	2.0
S	1.76	Al ₂ O ₃	16.3	FeO	0.2
N	0.33	Fe ₂ O ₃	2.8	CO ₂	44.3
Cl	0.75	TiO ₂	0.7		
O	10.01	MgO	0.4		
		Na ₂ O	0.8		
		K ₂ O	6.3		
		FeS ₂	12.3		
		SO ₃	0.5		
Total	100.00		100.0		100.0

Alongside with CO₂ emissions, Estonian energy sector also produces huge amounts of alkaline waste ash. About 5 million tons of oil-shale ash is transported to the ash fields annually. Oil-shale ash contains considerable amount of free CaO (10–25%, depending on the combustion technology). Contacting free lime with water leads to elevated pH-values (pH~13) and makes the ash landfilling by hydraulic transportation highly problematic. As a result, tens of millions cubic meters of alkaline water saturated with Ca²⁺-ions are being recycled between the plant and

the sedimentation ponds. Before directing the excess water to nature reservoirs, it should be neutralized so that its pH level would fit the environmental regulations (pH<9).

1.5. Summary of the literature review and aim of the study

The emission of GHGs and safe deposition/utilization of the solid wastes are among the most serious problems caused by the extensive usage of low-grade solid fuels in the world heat and power production. The CO₂ emissions could be decreased by reducing the use of fossil energy sources, improving the energy efficiency and/or by more intensive implementation of carbon capture and storage technologies. CO₂ sequestration by mineral carbonation, considering both natural minerals and alkali wastes as CO₂ sorbents, is a prospective option.

In the Republic of Estonia, the energy sector is predominantly (up to 67%) based on a locally-available low-grade carbonaceous fossil fuel, Estonian oil shale. Because of high share of the minerals present in the oil shale, big quantities of the alkali ash are formed (45–47 % of oil shale burnt, dry mass basis) and deposited in open-air ash fields. Depending on the combustion technology, the ash contains a total of up to 25% free Ca and Mg oxides; and therefore it can be considered a CO₂ binder even under natural weathering conditions. In consequence, the ash in question is rich in free lime as its most active component, and because of that it requires stabilization to assure a safe landfilling. Using CO₂ from flue gases as a neutralizing agent, the emission of CO₂ would be diminished.

The aims of this study were to estimate the CO₂-binding ability of the ash at different stages of its transportation and under different deposition conditions and to create a concept for abatement of the CO₂ emissions in Estonian oil shale-based power production using chemical-technological methods.

First, thermodynamical calculations were performed to evaluate the potential of CO₂ binding by the aqueous suspension of oil-shale ash and the theoretical amount of CO₂ bound by the oil-shale ash of average compositions. After considering the thermodynamical limitations, laboratory experiments were carried out to give thorough characterization of the ashes formed in the industrial-scale PF and CFBC boilers. The purpose was to study these ashes as sorbents for binding CO₂ from flue gases in aqueous mineral carbonation processes and to determine the main parameters of the following processes:

- direct one-step aqueous carbonation of the oil shale ash (the process rate determining mechanism was also elucidated);
- indirect aqueous carbonation of the oil-shale ashes by neutralizing the alkaline ash-transportation waters;
- natural weathering of the oil-shale ashes in open-air deposition conditions.

2. THERMODYNAMIC ANALYSIS OF THE REACTIONS OCCURRING IN THE SYSTEM OF ASH WATER SUSPENSION-FLUE GAS (*PAPER I*)

To elucidate the possibilities for reducing the CO₂ emissions, a thermodynamic analysis of the reactions that occur between the gaseous and solid combustion products formed at oil shale combustion was carried out (*Paper I*). Indeed, the thermodynamic analysis performed by calculating the changes in Gibbs free energy ΔG_T only estimates the probability to obtain certain equilibrium compositions in these systems, but gives no information about the limitations of phase contacting and mixing and about kinetic parameters, in particular the time necessary for reaching an equilibrium and the effect of activation energy. In this section, using the HSC software [80], equilibrium composition of the reaction products were calculated for a set of reactions occurring in the system of ash–water–flue gas.

Table 7: Compositions of the ash and flue gas forming at oil shale combustion

Amounts of the ash components contacted with liquid phase			Composition of the flue gas formed at oil shale combustion ($\lambda = 1.2$)			
Component	Content		Component	From organic part	From mineral part	Total
	%	mol/m ³

Equilibrium in the system ash pulp–flue gas

When performing the calculations, typical compositions of the ash and flue gas forming at oil shale combustion were used (Table 7). In the pulp, the solid : liquid mass ratio was 1 : 17.5. The compounds including Ca(OH)₂, CaSiO₃, Mg(OH)₂, SiO₂, CO₂, SO₂, CaCO₃, MgCO₃, CaCO₃*MgCO₃, CaMg(CO₃)₂, and characteristic species in solution such as Ca^(+2a), Mg^(+2a), Na^(+a), K^(+a), H₂CO₃^(a), HCO₃^(-a), CO₃^(-2a) and OH^(-a) take part in the reactions. Calculated amount of the flue gas bubbled through the ash pulp varied from 1 to 200 m³/m³. To describe the mole ratio of CO₂^(g) contacted with the pulp and free CaO present in the initial pulp, factor k was introduced.

As the amount of CO₂^(g) contacting with the ash pulp is less than CO₂^(g)-binding potential of the pulp (260-280 mol/m³), the CO₂^(g) is bound completely (Table 8).

At $k > 1.15$ (about 45 m³ of flue gas per 1 m³ of pulp), the ratio of the CO₂^(g) bound to the initial CO₂^(g) in the flue gas sharply decreases, and the amount of CO₂^(g) bound by 1 m³ pulp stabilizes on the level of CO₂^(g)-binding potential. The amounts of Ca and Mg hydroxides forming in the reaction of their oxides with water drop quickly when the amount of CO₂^(g) increases, whereas the amount of Ca(OH)₂ falls more rapidly than that of Mg(OH)₂. At first, much Ca is bound into a secondary silicate CaSiO₃, but its amount starts to decrease when more CO₂^(g) is passed. A possible explanation is the shift of equilibrium of the reaction towards the formation of CaCO₃ and SiO₂ at the temperatures below 250 °C (Eq. (13)). CaSiO₃ and Ca(OH)₂ are preferably used for CaCO₃ formation. After most of Ca is used to form CaCO₃ and the CO₂^(g)-binding potential is almost utilized, a formation of a complex carbonate starts and some more CO₂^(g) can be bound. Preferably CaMg(CO₃)₂ is formed, as the proportional amount of CaCO₃·MgCO₃ is some magnitudes lower (Fig. 4a). While forming complex carbonates almost all available Mg(OH)₂ is used up.

Figure 4. Equilibrium amounts of components (in moles per 1 m³ of ash pulp) depending on factor k: a – Ca compounds; b – Mg compounds; c – CO₂^(g) derivatives (Paper I).

The amounts of dissolved CO_2^- , CO_3^{-2} and HCO_3^- as well as of KHCO_3 and NaHCO_3 are small, below the $\text{CO}_2^{(g)}$ binding potential, but they start to increase at $k > 1.15$. The increase in amount of the flue gas is accompanied by a decrease in the solution alkalinity from $\text{pH} \approx 12.7$ to $\text{pH} \approx 8.5$. On this pH level the $\text{CO}_2^{(g)}$ binding by ash pulp ceases (Fig. 4c). Gaseous sulfur compounds $\text{SO}_2^{(g)}$ and $\text{SO}_3^{(g)}$ present in flue gas are completely bound, their equilibrium amounts are 10^{-36} or even less. Binding products are CaSO_4 and Na_2SO_4 , the amounts of other sulfates are negligible.

Table 8: Equilibrium in the system flue gas–ash pulp system depending on the flue gas proportion (*Paper I*).

Component or parameter	Fraction of the flue gas added to 1 m ³ of ash pulp, m ³							
	1	20	30	40	45	50	100	200
	Component amount, moles per 1 m ³ ash pulp							
k	0.03	0.51	0.77	1.02	1.15	1.28	2.56	5.1

pH	12.31	10.66	10.41	9.92	7.74	7.5	6.9	6.8

Diluting or concentrating the ash pulp in the range of 4.4–70 m³ of water per 1 ton ash causes only slow changes in the equilibrium compositions. Consequently, the fractional amount of the liquid phase is not critical for CO₂^(g) and SO₂^(g) binding.

Effect of the liquid phase pH on the CO₂ binding

In the case of all the processes where CO₂^(g) (from air or flue gas) is in contact with reaction products in the liquid phase, the following general regularities can be drawn:

- The CO₂^(g)-binding potential depends only on the amount of active components (especially, on the initial amount of Ca and Mg hydroxides) in the liquid phase, but not on the liquid : solid ratio.
- At high pH values (pH = 12–13), CO₂^(g) is bound completely, whereas the pH of the solution remains almost unchangeable. CO₂^(g) is bound mainly as CaCO₃, the formation of other carbonates is of less importance.
- Up to pH = 10–11 the contacted CO₂^(g) is bound completely. The pH value of the solution does not characterize the overall CO₂^(g)-binding capacity of the solution. The main product is CaCO₃.
- At pH ≈ 9, a decrease in the ratio of CO₂^(g) bound to contacted CO₂^(g) can be followed. CO₂^(g)-binding capacity is utilized to the extent of 90–95 %. Then the formation of CaMg(CO₃)₂ as well as of carbonic acid and its ions starts, and it can be followed by the increase in the amounts of NaHCO₃ and KHCO₃.
- At pH ≈ 8 the ratio of CO₂^(g) bound to contacted CO₂^(g) drops sharply, and the binding capacity is utilized to the extent of over 98 %. CaCO₃·MgCO₃ appears in the products: however, its role in CO₂^(g) binding is of a less importance as compared to the fractional amounts of CaCO₃ and CaMg(CO₃)₂. The increase in CO₂^(g) binding is mainly due to the growth of the amounts of dissolved CO₂^(a) and HCO₃^(-a).
- At pH ≈ 7.5 the CO₂^(g)-binding capacity (calculated from the initial content of free CaO and MgO) is completely utilized. Further binding is only due to the slow increase in the amount of dissolved CO₂^(a).

If equilibrium is reached, the CO₂^(g)-binding capacity of the oil shale ash is completely utilized in the system of flue gas–ash pulp (liquid–solid–gas). The main product formed during CO₂^(g) binding is CaCO₃, the role of other carbonates is of a lesser importance. At pH values 9–10, CO₂^(g) binding from the flue gas is complete. A decrease in pH to 8–9 indicates that the CO₂^(g)-binding potential of the pulp or water is almost utilized. The CO₂^(g)-binding capacities of ash pulp and of pond water are on the level of 260 moles and 60 or 30 moles (for a working pond or a pond in reserve) of CO₂^(g) per 1 m³ liquid phase, respectively.

The thermodynamical calculations performed show the prospects for CO₂ binding by the aqueous suspension of the oil shale ash and allow evaluating of the favorable pH-region of aqueous suspension and the theoretical amount of CO₂ bound by the oil shale ash of average compositions.

3. EXPERIMENTAL

3.1. Methods for characterization of the ashes

(Papers II, IV: Materials and Methods chapter)

Ash samples were collected from different points within the ash-separation systems of the CFBC and PF boilers at the Estonian Power Plant. The samples were marked as follows:

- for CFBC: bottom ash CFBC/BA, intrex ash CFBC/INT, economizer ash CFBC/ECO, air preheater ash (CFBC/PHA), electrostatic precipitator ashes (taken from the 1st to 4th fields) CFBC/ESPA1-4 and a mixture of the ashes taken from the ash silo CFBC/Mix;
- for PF: bottom ash PF/BA, superheater ash PF/SHA, economizer ash PF/ECO, cyclone ash PF/CA and electrostatic precipitator ashes (taken from the 1st to 3rd fields) PF/ESPA 1-3

All ash samples were analyzed to determine chemical, fractional and phase composition and morphology and specific surface area (Table 9).

Table 9: Methods for characterization of initial materials and reaction products

Properties	Characterization method
Chemical composition ¹	Chemical analysis of the solid phase: total CaO (slightly modified EVS-EN 196-2:1997), free CaO [81], CO ₂ (volume method, GOU-1 gas analyzer), total MgO (AAS), total S and its bonding forms (EVS 644:1995), loss on ignition (EVS 669:1996), moisture content (EVS-EN 12048:2000); Chemical analysis of liquid phase: pH, contents of Ca ²⁺ , Mg ²⁺ , SO ₄ ²⁻ (Spectrodirect spectrophotometer), alkalinity (ISO 9963-1:1994(E)), TDS (HI9032 microprocessor conductivity meter)

3.2. Experimental device for aqueous carbonation of oil shale ash

Batch mode (Papers III, IV: Materials and Methods chapter)

PF ashes, CFBC ashes and model compounds corresponding to oil-shale ash components, such as CaO, Ca(OH)₂, MgO, Mg(OH)₂, CaSiO₃, Ca₂SiO₄, Ca₃Mg(SiO₄)₂, (Ca,Na)₂(Mg,Al)(Si,Al)₃O₇, MgSiO₃ and Mg₂SiO₄, were carbonated in aqueous suspensions in order to evaluate their binding potential as well as the process rate controlling mechanism. Experiment conditions are shown in Table 10. Carbonation of the ash–water suspensions and model compounds was carried out using a model gas whose composition simulated the proportion of CO₂ in flue gases as formed during the oil shale combustion. Carbonation was performed in a glass absorber (diameter 55 mm, water column height 60 or 500 mm) under atmospheric pressure (Fig. 5a).

Note: EPP = Estonian Power Plant, BPP = Baltic Power Plant

The degree of the carbonation N_{CO_2} that indicates how many times the amount of CO_2 entrained into the suspensions exceeds the stoichiometric ratio ($CaO/MgO + CO_2 = CaCO_3/MgCO_3$) varied up to 6. After the carbonation, the suspension was filtered and the solid residue was dehydrated at $105^\circ C$. Then both phases were analyzed for chemical composition (Tables 9 and 10). The efficiency of the carbonation process was described by the degree of CO_2 -binding BD_{CO_2} (*Paper III: Eqs (1) and (2)*). To study the process of deceleration, i.e. the mechanisms that slow down the carbonation process, the samples were also analyzed for specific surface area, surface characteristics and elemental composition.

Continuous mode (Paper V: Materials and Methods chapter)

The continuous-mode aqueous carbonation was optimized by adding reactor-columns (water column height 0.7 m and volume 10 L) working in cascade and setting the pH levels in different reactors in the range of alkaline to almost neutral, prolonging herewith the contact time of the phases (ash, water, CO_2 -containing model gas) at optimal conditions for $CaCO_3$ precipitation (Fig. 5b). Ash and water (tap water or circulating process water) were fed to the first reactor-column from which the partly carbonated suspension was led to the next stages for deeper carbonation. The pH of the suspension was controlled by adjusting the flow-rate of incoming CO_2 . Samples collected from the bottom side of reactor-columns were filtered and the solid residue dehumidified at $105^\circ C$. The liquid and solid phases were analyzed for chemical composition (Tables 9 and 10). The effectiveness of the carbonation process was described by the CO_2 -binding degree and the CaO-binding degree (*Paper IV: Eqs. (1–3)*).

3.3. Experimental set-up for CO_2 binding by alkaline wastewater

Dispergator-type phase mixer (Paper V: Materials and Methods chapter)

Neutralization of the alkaline ash transportation water from the ash transportation system of the Estonian Power Plant ($Ca^{2+} = 800\text{--}1020$ mg/l; pH = 13.0–13.1) was carried out in a laboratory dispergator-type batch device (Fig. 5d, Table 10), which provided an effective mechanical mixing of the gas and liquid phases as to increase the interfacial contact surface [84]. The initial ash-transportation water was treated with model gases: FG 1 (15% CO_2 in the air) or FG 2 (15% CO_2 and 0.07% SO_2 in the air). The treated waste-water had pH = 10 after 1 carbonation cycle at CO_2 excess $N_{CO_2} = 1.5$ (the amount of CO_2 passed per the stoichiometric amount according to Eqs (1) and (2) in *Paper V*) and pH = 8 after 3 cycles ($N_{CO_2}=4.5$). The contact time of phases was 1.25-3.75 sec. After separation of the liquid and gas phases the gas was directed into the atmosphere and the liquid phase was either led back into the reactor or sent to filtration, where the solid reaction product was separated and dried at $105^\circ C$.

Barboter-type column (Paper V: Materials and Methods chapter)

To compare different technological approaches, also a conventional barboter-type column (Fig. 5c) was used. The experiments lasted until the pH of the treated

wastewater reached pH=10 or 8. The gas phase was analyzed by a TESTO 350 gas analyzer to determine the residual concentration of SO₂. After treatment the suspension was filtered and the solid residue was dehumidified at 105°C. The liquid and solid phases were analyzed for chemical composition and/or for surface properties and particle size distribution (Tables 9 and 10).

Figure 5. Experimental setups for an aqueous carbonation of the waste ash (a, b) and for an alkaline wastewater carbonation (c, d).

3.4. Experimental setup for a natural CO₂ binding by oil shale ashes

Paper III: Materials and Methods chapter

Model experiments of CO₂ binding in the natural open-air conditions were carried out using CFBC ashes, PF ashes and as a mixture of the two. Initially, the CFBC ash contained 7.10–7.93% CaO_f, the PF ash contained 0.90–1.00% CO₂ and 15.23–20.45% CaO_f and the mixture (50% CFBC ash + 50% PF ash) contained 4.30% CO₂ and 11.17% CaO_f. The ashes were mixed with water (phase ratio 1 : 5 was used to imitate the hydro ash removal and 1 : 0.3–0.9 to imitate the dense slurry technology) and the mixture was loaded into sample holders. These sample bodies were held under summer, autumn/spring and winter temperature conditions (Table 10). After given intervals (1–8 weeks), the sample bodies were taken out of the holders and divided into 6 layers (á 1cm). The layers were dehydrated at 105°C and analyzed for chemical composition (Table 10). The data obtained was used to calculate the amounts of CO₂ and free CaO bound during the experiment (*Paper III: Eq. (3)*) as well as the binding degree (*Paper III: Eq. (4)*).

4. RESULTS AND DISCUSSION

4.1. Characterization of oil shale ashes formed in industrial-scale boilers (*Paper II*)

4.1.1. Chemical and phase composition

For the ashes used in the tests, the sharp difference in the operating temperature and fuel particle size [45] results in different behavior of calcium- and sulphur-containing compounds (Table 11 and also *Paper II: Tables 1 and 2*).

Table 11: Characteristics and composition of the oil-shale ashes formed in CFBC and PF boilers

Due to a considerably higher temperature (up to 1250–1400 °C) when using the PF combustion technology, the rate of the carbonate decomposition is as high as 97–98%, while it is moderate (47–96%) in the case of CFBC technology (boiler temperature 720–800°C). The content of free CaO is higher in the PF ashes (up to 24.84%), while in the case of the CFBC ashes it is relatively high only in the intrex ash (18.87%), but decreases considerably in the electrostatic precipitator ashes (down to 2.82%). In both the CFBC ashes and PF ashes the content of the total CaO decreases and the content of the indissoluble residue increases along the ash separation system.

In the case of the CFBC (Table 11 and *Paper II: Table 1*), the binding of the gaseous SO₂ occurs in the combustion chamber and the intrex of the boiler. It leads to forming a high sulphur content of the bottom ash (4.53% S) and the intrex ash (7.76% S). The major part of the sulphur is bound to sulphates; only traces of sulphides can be found in the samples taken from the beginning of the ash separation system of the CFBC boilers. In the case of PF, the bound sulphur is more uniformly distributed between the different types of ashes and it is the highest in the precipitator ashes (3.67%, *Paper II: Table 2*).

Quantitative XRD measurements (Table 11 and *Paper II: Tables 5 and 6*) verified the results of the chemical analysis. Compared to the PF ashes, the CFBC ashes contain more calcite and less free lime. Mg was found in both cases mainly as periclase (MgO), and also partially bound to carbonates (dolomite can be found in CFBC bottom ash) or silicates (merwinite, melilite). In the CFBC ashes, the silica compounds are mainly presented by quartz and orthoclase-type K-feldspar, while the PF ashes contain noticeably more secondary silicate – belite and merwinite. A relatively higher content of the secondary silicates can be explained by significantly higher temperatures used in the PF boilers, which leads to the formation of melted phases initiating the reactions between free CaO and quartz or silicates.

4.1.2. Particle size distribution

The particle size of the CFBC ashes varies in a very wide range (Fig. 6, *Paper II: Table 3*). The bottom ash is the coarsest one (~45% of the particles have a diameter of >0.63 mm), the intrex ash particles are an average size (90% of the particles have a diameter of 0.4–0.045 mm) and the electrostatic precipitator ashes are the finest (85–95% of the particles have a diameter less than 0.045 mm). An article distribution of the PF ashes (Fig. 6, see also *Paper II: Table 4*) is more homogeneous with few particles having a diameter over 0.63 mm.

The above-mentioned dissimilarities in the chemical and fractional compositions of the different ash types observed for various combustion technologies are caused by several circumstances, the particle size composition of the fuel fed to the boiler being the most important of them. For the PF boilers, an average median measure of the fuel fed to the boiler is 35–60 µm, and the rest on sieves with aperture size 90 and 200 µm is 20–40 and 10–25%, respectively. The fractions differ noticeably by their chemical composition [45]. The material fed to the CFBC boilers belongs

predominantly to the size range 1–10 mm. Fine particles of the pulverized oil shale and ashes melt and agglomerate forming larger particles, while in the case of the CFBC, the main part of fine fractions is formed as a result of the intensive attrition of particles in the fluidized bed.

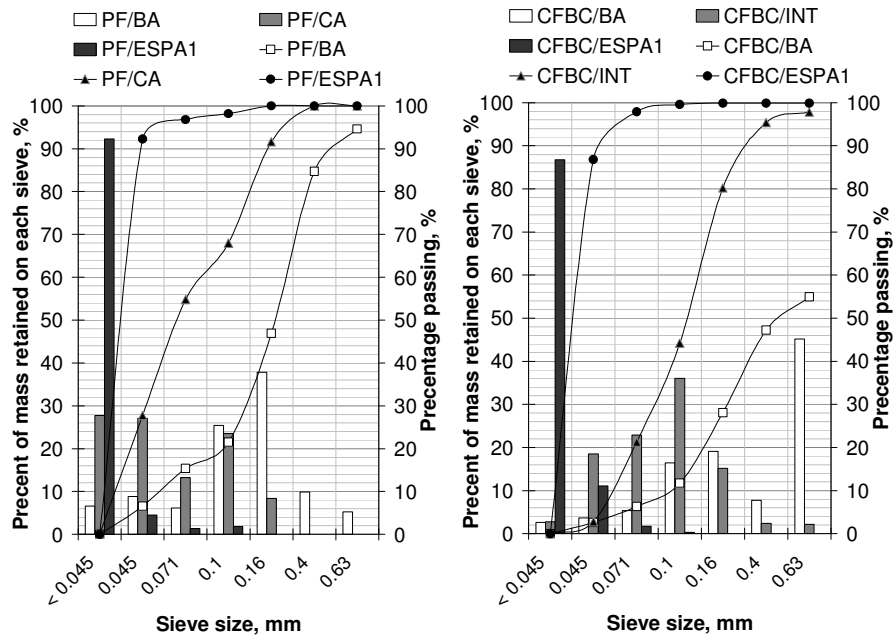

Figure 6. Grain-size composition of PF ashes and CFBC ashes.

4.1.3. Physical structure and surface characteristics

Comparison of SEM photos of the ash samples shows that particles of the CFBC ashes formed at moderate temperatures (750–800°C) are characterized by an irregular shape as well as by a porous and uneven surface (Fig. 7a, Paper II: Fig. 2). A glassy phase is not formed.

Figure 7. SEM pictures of (a) CFBC/ESPA1 and (b) PF/CA, magnification 2000×.

In the case of PF ashes, the glassy phase significantly affects the formation of the particle shape and surface properties: the particles are characterized by a regular

spherical shape with a smooth surface (Fig. 7b, *Paper II: Fig. 3*). It was shown that along the ash separation system the porous irregular-shaped particles are replaced more and more by regular smooth spherical particles (an electrostatic precipitator ash).

BET measurements (Table 11 and *Paper II: Tables 1 and 2*) showed significant differences in the physical structure of the CFBC ashes and PF ashes: depending on the ash type, the differences in SSA were up to a factor of ten times. While the specific surface area of the CFBC ashes can reach 8.00 m²/g, the SSA of the PF ashes is within the 0.36–1.75 m²/g range. This is caused by more intensive sintering of the PF ashes at boiler temperatures. Pore distribution analysis of the ashes showed that the pore volume of the CFBC ashes (CFBC/ESPA1) is contributed by a wide range of pores ($D_p > 2$ nm), while for the PF ashes (PF/CA) the dominating pore diameter is considerably smaller – below 3 nm (Fig. 8). Thereby, the PF ashes are expected to be more extensively influenced by the formation of reaction products on the surface of particles and by pore plugging. This could reduce mass transfer rates.

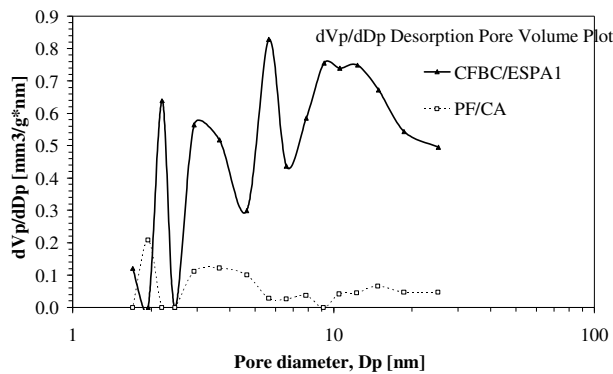

Figure 8. Pore distribution of the PF ashes and CFBC ashes (*Paper III*).

Thus, the reactivity of waste ashes towards CO₂ is determined by their chemical and phase composition as well as by the physical structure of the ash particles. Oil shale ashes formed in the boilers operating at different combustion technologies differ significantly in their chemical and phase compositions as well as by surface properties.

4.2. Concept of CO₂ mineralization by the oil shale waste ash (*Paper III*)

Based on our investigations relating to the characteristics and reactivity of the oil shale ashes as well as on the literature data, the oil shale ash could be qualified as a sorbent for CO₂ aqueous sequestration. A concept of the CO₂ mineral sequestration by waste oil shale ash has been generalized in Fig. 9, where the proposed technological methods are outlined.

The process of ash hydro-separation and depositing is currently in a rather basic state: the ash is hydro-transported into wet open-air deposits, where the solid particles precipitate and the excessive water drains to the lower part of the ash field. After sedimentation the draining water is led back to the beginning of the cycle through a back-flow channel. Together with transportation of the ash particles, other processes including lime slacking, dissociation of forming portlandite and dissolution of different salts also occur. As a result tens of millions cubic meters of alkaline water (pH level 12–13) saturated with Ca^{2+} , K^+ , SO_4^{2-} and other ions is recycling between the plant and the sedimentation ponds. In consequence, a certain amount of CO_2 is bound from the air by alkaline transportation water and by the ash during hydraulic transportation and open-air deposition.

Figure 9. Concept of CO₂ mineral sequestration by a waste oil shale ash (Paper III).

According to our initial estimates, the amount of CO₂ emitted during the oil shale-based heat and power production could be diminished by intensification of the natural CO₂-binding processes that occur during ash transportation and deposition. The most extensive effect could be achieved by treating the ash–water suspensions and the ash transportation waters with CO₂-containing flue gases. CO₂ dry binding in the flue gas channel by the oil shale ash [43] has not been a subject of the current investigation.

4.3. Transformations and CO₂ binding in the heterogeneous system CO₂–Ash–Water

Transformations in the heterogeneous system CO₂–oil-shale ash (PF)–water were experimentally first described in one of our earlier papers [40]. Basing on thermodynamic calculations (Paper I), the pH of suspension was chosen as a main indicator for describing and directing the carbonation process in an aqueous media. The binding properties of different types of ashes (Paper II) in batch mode, as well as the binding potential of various oil-shale ash components were evaluated and presented in Paper III. The behavior of lime as the key component of ash in various conditions was studied and the mechanism of the process deceleration

proposed in *Paper IV*. As the next step, a laboratory-scale continuous-flow reactor system for aqueous carbonation of oil-shale ash was worked out and preliminary results were presented in *Paper IV*.

4.3.1. Batch reactor (*Paper III*)

4.3.1.1. Model compounds

The CO₂-binding potential of various oil-shale ash components was evaluated in aqueous carbonation experiments with model compounds including CaO, Ca(OH)₂, MgO, Mg(OH)₂, CaSiO₃, Ca₂SiO₄, Ca₃Mg(SiO₄)₂, (Ca,Na)₂(Mg,Al)(Si,Al)₃O₇, MgSiO₃ and Mg₂SiO₄. The experimental setup and conditions are presented in Chapter 3.2. The duration of the carbonation experiments was 20–40 min, during which 3–5 times the stoichiometric amount of gaseous CO₂ (N_{CO₂}) was contacted with the suspension (100 mL).

Figure 10. Extent of CO₂-binding at aqueous mineral carbonation of CFBC ash, and PF ashes and model compounds (*Paper III*)

The results of the binding experiments indicated that:

- CaO and Ca(OH)₂ were the most active toward CO₂. The BD_{CO₂} of these compounds was close to 100% (Fig. 10).
- Ca-silicates also displayed a good CO₂-binding efficiency under the experimental conditions (atmospheric pressure and room temperature): CaSiO₃ reached up to 88.7% and Ca₂SiO₄ up to 76.4% of their maximal CO₂-binding potential (Fig. 10). Reactivity of the synthetic/secondary compounds differed significantly from that of the natural minerals, which were treated with CO₂ at 160°C and under 20 bar [15]. Changes that occur with the belite particle as a result of aqueous carbonation are shown in Fig. 11: the Ca-content inside the particle decreases (Fig. 11b) and Ca precipitates on the particle surface as a CaCO₃ layer (Fig. 11c).
- MgO showed a moderate CO₂-binding activity: the BD_{CO₂} varied from 36.9 to 61.2% (Fig. 10). A freshly-synthesized MgO_{fr} possesses a higher CO₂-binding degree than a commercially purchased MgO_r.

- The CO_2 -binding ability of $\text{Ca}_3\text{Mg}(\text{SiO}_4)_2$ was considerably lower ($\text{BD}_{\text{CO}_2}=20.6\%$). We expected that under the experimental conditions melilite and Mg-silicates would not be active toward CO_2 . According to the literature data, Mg-silicates are much more stable than Ca-silicates, as the bonds inside the Mg-silicate molecule are difficult to break in these mild conditions [86]. Therefore, in addition to free lime, Ca-silicates CaSiO_3 and Ca_2SiO_4 , and periclase MgO should also be taken into account while calculating the maximal CO_2 -binding potential of oil-shale ashes.

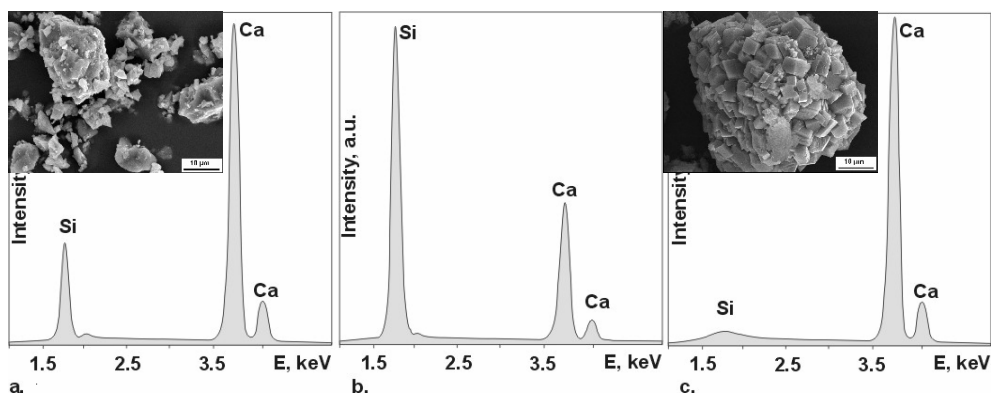

Figure 11. EDX analysis of a belite particle before (a) and after carbonation (b-inside the particle and c- crystals on the particle surface) (presented at GHGT-8 [85])

4.3.1.2. Comparison of CFBC ash and PF ash

The experimental setup and conditions are presented in Chapter 3.2. The duration of the carbonation experiments was 30–90 min, during which 1.2–6 times the stoichiometric amount of gaseous CO_2 (N_{CO_2}) was contacted with the ash suspension (600 mL).

Laboratory batch tests demonstrated that oil-shale ashes formed in boilers using different combustion technologies differ noticeably in their reactivity towards CO_2 in aqueous suspensions (Table 12; Fig. 10), as well as in the amount of CO_2 bound.

Compared to the PF ash, it is possible to carbonate the CFBC ash to a greater extent; in most cases it is possible to lower the pH of the aqueous suspensions of its solid residue below $\text{pH} = 9$ (Table 12, with the exception of CFBC/BA – full carbonation is apparently inhibited due to the coarse fractional composition, Fig. 6b). This parameter is important in reference to deposition of carbonated ash. Higher pH values (10.9–11.9) result from a higher free CaO content (0.57–3.47%) in the solid residues of the carbonated PF ashes. Apparently, the lack of porosity in PF ashes limits the availability of a portion of free CaO for reaction with CO_2 .

The degree of binding calculated on a free CaO basis ($\text{BD}_{\text{CO}_2}^*$) exceeds 100% for both CFBC ash (140–160%) and PF ash (110–180%). This is explained by the fact that components such as Ca-silicates and MgO present in the oil-shale ash also take part in CO_2 -binding reactions. When additional CO_2 -binding components like

free MgO, CaSiO₃, and Ca₂SiO₄ are taken into account, BD_{CO₂} reached 83–98% for CFBC ash and 48–73% for PF ash. However, due to the lower content of free CaO, the CO₂-binding capacity of CFBC ashes in the aqueous carbonation process was lower. The amount of CO₂ bound by 1 t of ash depended on the process conditions, reaching ~160 and 100 kg for PF ash and CFBC ash, respectively (Table 12). The total amount of CO₂ present in the ash after treatment averaged up to 170 kg/t.

Table 12: Composition of the carbonized solid phase and some characteristics of the process (*Paper III*)

Ash type	CO ₂	CaO _f	BD* _{CO₂} ¹	BD _{CO₂}	pH ²	CO ₂ bound, kg/ash, t

4.3.2. Process rate-determining mechanism (*Paper IV*)

As shown in the previous chapters, the operating conditions of PF and CFBC boilers significantly affect the composition, physical structure, particle surface properties and, in its turn, chemical reactivity of the forming ashes. In the context of CO₂ sequestration and ash stabilization, the availability of lime for hydration and carbonation reactions is of a key importance.

Low porosity and small-size pores in PF ashes limit the availability of free lime among other components for reaction with CO₂, which can easily lead to process deceleration. Therefore, to study process deceleration in the heterogeneous system ash - water - CO₂, the PF cyclone ash was chosen as the least porous but also the most typical PF ash (it amounts to 60% of the total PF ash produced). CFBC/Mix12 ash sample was taken to represent the CFBC ashes for comparative experiments. Next, simplified distilled water based batch systems as described above do not correspond to the real continuous-flow processes, where the suspension liquid phase is continuously saturated with different salts leached from the heterogeneous composition of oil-shale ashes. Therefore, distilled water (DW), recirculation water (RW; pH = 13; TDS = 11.4 g/L; Ca²⁺ = 730 mg/L; SO₄²⁻ = 2.8 g/L; OH⁻ = 64.25 mmol/L) from the ash separation system of the Estonian Power Plant and carbonated recirculation water (CRW; pH = 7.5; TDS = 6.8 g/L; Ca²⁺ =

450 mg/L; $\text{SO}_4^{2-} = 2.7 \text{ g/L}$; $\text{HCO}_3^- = 60.75 \text{ mmol/L}$) were used as liquid agents in comparative experiments.

Figure 12. Different types of the particles present in PF cyclone ash (PF07/CA) and their chemical composition (Paper IV)

Figure 13. Reactions of lime at CO_2 aqueous sequestration by oil-shale ash (Paper IV)

When PF/CA is immersed into DW, slaking of lime-containing particles (Fig. 12b,c) occurs. As the water penetrates into the surface pores, heat of hydration is released and this exerts internal expansive forces in the lime-containing particles (the molar volumes of $\text{Ca}(\text{OH})_2$ and CaO are 33.078 and 16.79 mL/mol, respectively [80]). This causes the particles to fracture and disintegrate (Fig. 15a). The conversion of CaO to $\text{Ca}(\text{OH})_2$ is followed by the dissolution of $\text{Ca}(\text{OH})_2$ to give Ca^{2+} -ions and OH^- -ions at the surface of the particles and finally, by the diffusion of Ca^{2+} - and OH^- -ions into the bulk of solution (Fig. 13) [68, 70]. The solution becomes deeply alkaline ($\text{pH} = 12.9$) and oversaturated with Ca^{2+} -ions ($\text{Ca}^{2+} = 1,400\text{--}1,500 \text{ mg/L}$, Table 13). The homogeneously melted particles (Fig. 12a) are not affected by hydration (Paper IV: Fig. 5a) and are not likely to participate in carbonation reactions during short reaction times (15–45 min) at mild conditions (room temperature, atmospheric pressure, 10% CO_2 in model gas mixture).

As CO_2 -containing model gas is bubbled through the ash–water suspension, CaCO_3 precipitation reaction takes place (see Fig. 13). During carbonation, the pH

and concentration of Ca^{2+} -ions in the liquid phase stay on a high level until almost all free lime is realized (~2% of unreacted lime in the solid residue, Table 13; Fig. 14a,b). Then the pH of the suspension liquid phase and the concentration of Ca^{2+} -ions decrease rapidly until stabilizing at pH~7.5 and $\text{Ca}^{2+} = 300 - 400 \text{ mg/L}$ (Table 13, Fig. 14a). After carbonation (the solid residue contains 30–36% CaCO_3) the ash particles are covered with a porous and permeable product layer (Fig. 15c), as SSA increased to 10–13 m^2/g (see Table 13).

Table 13: Carbonation of the aqueous suspensions of oil-shale ash: composition of the solid and liquid phases (*Paper IV*)

N.a. - not analyzed

Figure 14. Carbonation of the aqueous suspensions of PF ash (PF07/CA): Dependences of (a) Ca^{2+} content and pH of the liquid phase and (b) CO_2 and free CaO contents in the solid phase on the extent of carbonation (N_{CO_2}) (Paper IV)

Figure 15. SEM images of PF ash (PF07/CA) immersed into DW (a) or into CRW (b) and carbonated in the heterogeneous systems of (c) PF07/CA + DW + CO_2 containing model gas or (d) PF07/CA + CRW + CO_2 -containing model gas

Using the recirculation process water that contains an excess amount of SO_4^{2-} and/or HCO_3^- -ions (RW or CRW), significantly inhibits the lime-slaking rate and the following reactions. When PF/CA ash is immersed into the carbonated recirculation water (pH ~ 7.5, $\text{HCO}_3^- = 60.75 \text{ mmol/L}$; $\text{SO}_4^{2-} = 2.7 \text{ g/L}$) Ca^{2+} -ion concentration in the liquid phase drops to 60–140-mg/L (see Table 13) according to the following reaction (Eq. (14)):

This indicates that hydration of the lime-containing particles is already retarded.

As it was shown in Chapter 1.3.1, the presence of Ca^{2+} and OH^- -ions in the slaking water decelerate the diffusion of $\text{Ca}(\text{OH})_2$ away from the particles' surface, thus reducing the slaking rate of lime [70]. Carbonate and sulfate ions are known to form insoluble layers of both CaCO_3 and CaSO_4 . These layers partially or completely coat the particles and prevent their further dissolution or slow it down [72, 73]. The SEM and EDX linescan analysis reveals that immersing ash particles into the sulfate-containing recirculation water causes the sulfur compounds (obviously in the form CaSO_4) to concentrate in the surface layer (Fig. 16a,b). The layer of carbonates cannot be detected by the EDX linescan analysis because the base material also contains carbon, but the solid phase analysis shows a slight increase in CO_2 percentage (1.1–1.5→2.6–3.1%, see Table 13). The small-size pores of PF ash are easily blocked although the overall SSA may increase (0.4–0.5→1.1–2.2 m^2/g ; see Table 13) as a result of the precipitating reaction products (CaSO_4 , CaCO_3). Surface observations also showed distinct differences between ash particles immersed into DW and CRW: instead of a hydrated surface layer formed by particle fracturing (see Fig. 15a) the cleavage of reaction products on the surface of particles seems to be more of the case (Fig. 15b).

The carbonation process decelerates shortly after introducing the CO_2 -containing gas mixture into the ash–water (CRW, RW) suspension. The pH and Ca^{2+} content in the liquid phase decrease rapidly (Fig. 14a), the final product contains only 6–7% CO_2 and most of the free lime (17–18.5%) remains unreacted (Fig. 14b; Table 13). Process deceleration, which starts already during the hydration step, is the combined effect of the two factors: a low porosity of the PF ash and a high content of sulfate and/or carbonate ions in the suspension liquid phase. Due to the high concentrations of the dissolved salts in recirculation water, the diffusion of $\text{Ca}(\text{OH})_2$ away from the surface decelerates, which, in its turn, reduces the slaking rate and causes the reactions to take place inside the pores. Insoluble layers of the precipitating reaction products easily plug the small-size pores of PF ash (see Fig. 13). The forming product layer is characterized by a crystalline and impermeable nature (Fig. 15d). Therefore, while operating with the continuous-flow reactor, the composition of the liquid phase contacted with the ash should be monitored and the production of carbonate/bicarbonate ions avoided.

Hydration of PF ash by water (PF08/CA hydr) or by the air moisture (PF07/CA*), which can be considered as a pretreatment, causes the ash particles to fracture and to disintegrate. In turn, the SSA of the ash as well as pore size

increases [86] and lime becomes increasingly available for the carbonation treatment (see Table 13). As a result, the aqueous carbonation process becomes less influenced by the composition of the liquid phase and the final product contains less unreacted free lime (1.97–6.97%; see Table 13).

Figure 16. SEM and EDX analysis of PF ash (PF07/CA) after (a) immersing into CRW and (b) treatment with CO₂-containing model gas (*Paper IV*)

The porous structure of the CFBC ash particles supports fast and full hydration of lime as well as diffusion of Ca²⁺-ions into solution. This results in almost complete carbonation. The outcome of carbonation does not depend on the liquid phase compositions, and the solid phase composition is almost identical to that of the systems using DW or RW (containing 16.58–16.99% of CO₂ and 1.17–1.26% of CaO_f; see Table 13). In both cases the surface is covered with a fluffy and permeable product layer (*Paper IV: Fig. 7c,d*).

4.3.3. Continuous-flow reactor (*Paper IV*)

Continuous-mode carbonation of oil-shale waste ashes was carried out at given pre-set pH ranges. The liquid phase compositions used corresponded to the suspension pH and gave rather similar results with both types of ashes. In coordination with the high pH level of the 1st reactor, the liquid phase was oversaturated with Ca²⁺-ions (1,100–1,500 mg/L; Fig. 17). Thus, the most suitable conditions for CO₂ absorption were created. In the case of CFBC ash, the solid phase from the 1st reactor contained 4–5% of unreacted lime and 14–16% of CO₂. This indicated that 65–70% of initial free CaO was utilized (BD_{CaO}, Fig. 18,*a*).

These indicators were somewhat lower in the case of the carbonated PF ash, which contained over 8% of unreacted lime. This shows that a 55–65-percent utilization of free CaO was achieved (BD_{CaO} , Fig. 18,*b*).

Figure 17. Changes in Ca^{2+} -ion concentrations and the pH of the suspension liquid phase during carbonation of (a) - CFBC ash and (b) - PF ash in a continuous mode (Paper IV)

The carbonation process was continued in the 2nd reactor, where the pH and the content of Ca^{2+} -ions in liquid phase decreased to 10–11 and 500–800 mg/L, respectively. After the 2nd reactor about 80–90% of the initial free lime was utilized. On the final stage (3rd reactor) of ash carbonation process, the suspension pH decreased to 7.5–9 and BD_{CaO} stabilized on the level of 95 and 90% for CFBC ash and PF ash, respectively (Fig. 18).

Somewhat higher values of BD_{CO_2} (they often occurred to be over 100% in the 3rd reactor, although free lime was not completely utilized) compared to BD_{CaO} showed that other potentially CO_2 -binding components of ash, such as MgO and Ca-silicates, took part in CO_2 -binding reactions (BD_{CO_2} ; Fig. 18,*a*). This tendency was not as apparent in the case of PF ash (Fig. 18,*b*). Although switching from tap-water to circulating process-water (pH = 8–10; Ca^{2+} = 400–700 mg/L; SO_4^{2-} = 1,000–1,600 mg/L; TDS = 1.0–1.7 g/L; CO_3^{2-}/HCO_3^- = 1.5–3.5 mmol/L) did not have any noticeable effect on the CFBC ash carbonation, it had a decelerating influence on the processing of PF ash (the percentage of unreacted lime increased from 1.7 to 2.9%). Evidently, in the case of PF ashes as non-porous materials [86]

some part of free CaO is not accessible under these conditions. The final products contained 0.6–2.9% unreacted lime and 17–20% of CO₂.

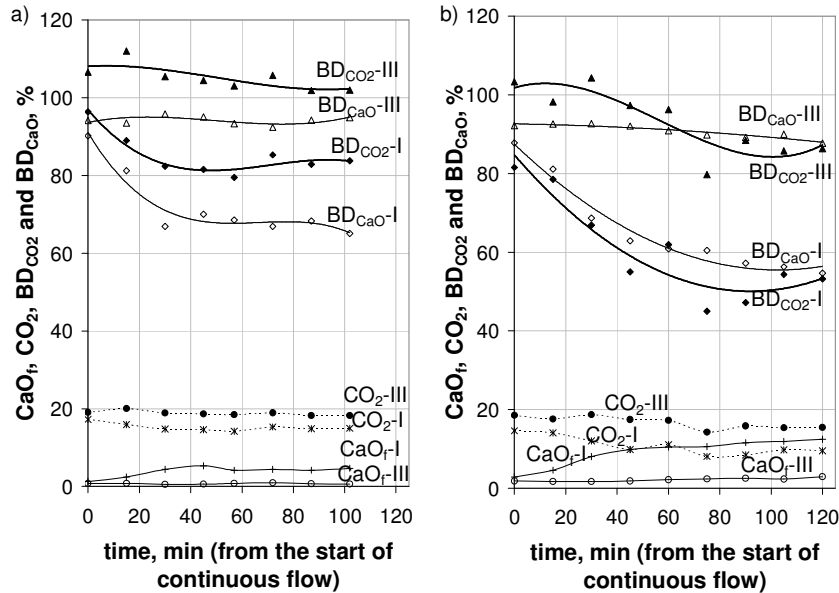

Figure 18. Changes in CaO_f and CO₂ contents and CO₂- and CaO-binding degrees during carbonation of a - CFBC and b - PF ash in continuous mode

All in all, the stability of the process of continuous-mode oil-shale waste ashes carbonation in this laboratory-scale set-up at optimal conditions was achieved for Ca(OH)₂ dissociation and CaCO₃ precipitation. The experiments confirmed significant differences in the reactivity of CFBC ash and PF ash towards CO₂. While the CFBC ash was carbonated almost completely in a continuous-flow reactor system, the PF ash probably needs a pre- or extended treatment for a deeper carbonation. The pretreatment of the pulverized-fired ash by grinding or hydration would make the free lime trapped inside the ash particles more accessible for reagents due to breaking the particles and/or increasing their porosity. Also, it is important to closely monitor the contents of sulfate and carbonate ions in the contacting liquid phase, which form insoluble product layers on the surface of particles and thereby strongly inhibit the ash-hydration process.

4.3.4. Conclusions

Experiments involving CO₂ mineral sequestration by ash–water suspensions demonstrated that both ash types qualify as effective sorbents for CO₂ capture in an aqueous mineral carbonation process, as they are able to bind 100 to 160 kg CO₂ per 1 t of ash.

Batch experiments:

- As expected, free CaO is the main CO₂-binding component in ash. But in addition to free lime, the Ca-silicates (CaSiO₃ and Ca₂SiO₄) and periclase should also be taken into account while calculating the maximal CO₂-binding potential of oil-shale ashes.
- Under the same conditions, CFBC ash is able to be carbonated to a greater extent compared to PF ash: BD_{CO₂} values are 83–98 and 48–73%, respectively. Also, compared to PF ash, the CFBC ash can be carbonated more deeply by lowering the pH of the aqueous suspension of the solid residue, in most cases below pH = 9. In the case of non-porous PF ashes, a part of the free CaO remains unreacted and this leads to the elevated pH-values (11–12) causing environmental issues upon depositing.

Process rate-determining mechanism:

- Aqueous carbonation of PF cyclone ash, which is considered the most typical PF ash, depends to a great extent on the aqueous phase composition. In the case of the PF ash–recirculation water system, which is characterized by an excess amount of sulfate and/or carbonate ions, the process decelerates shortly after introducing the CO₂-containing model gas and most of the free lime (17–18.5%-Abs) remains unreacted.
- Process deceleration, which starts already at the hydration step, is mainly caused by concurrence of the two factors: a low porosity of PF ash and a high content of sulfate and/or carbonate ions in the liquid suspension phase. Due to the high concentration of dissolved salts in the recirculation water, the diffusion of Ca(OH)₂ away from the particles` surface decelerates. This, in turn, reduces the slaking rate and causes the reactions to take place inside the pores. Precipitating reaction products easily plug the small-size pores of PF ash. In the slaking water, carbonate ions and sulfate ions in form insoluble layers of both CaCO₃ and CaSO₄. These layers partially or completely coat the particle and prevent further dissolution of CaO.
- Porous structure of CFBC ash particles supports fast and full hydration of lime as well as diffusion of Ca²⁺-ions into solution. This results in almost complete carbonation. The effect of the liquid phase composition on the slaking and diffusion rates of Ca²⁺-ions and the following carbonation reaction is not evident.

Continuous flow experiments:

- A continuous-mode laboratory-scale reactor system for treating the oil-shale ash–water suspensions with CO₂-containing model gas was developed. The carbonation process was optimized by introducing the cascade mode of operation of the reactor-columns. The pH levels in different reactors were ranged from alkaline to almost neutral. This enabled optimal conditions for lime slaking, Ca(OH)₂ dissociation and CaCO₃ precipitation.
- The experiments confirmed significant dissimilarities in the reactivity towards CO₂ of water-suspended oil-shale ashes formed under different combustion regimes. While the CFBC ash is carbonated almost completely in the

continuous-flow reactor system, the PF ash needs pre- or extended treatment for deeper carbonation. Final products contained 0.6–2.9% wt. of unreacted lime and 17–20% wt. of bound CO₂.

4.4. CO₂ binding by alkaline ash transportation water (*Paper V*)

Intensifying the natural CO₂-binding potential of the alkaline ash-transportation water by using aeration or sprinkling technologies to bind CO₂ from the air gave moderate results [87].

Binding CO₂ from the flue gases by the alkaline ash-transportation water was discussed further in *Paper V*. The intensity of the alkaline wastewater neutralization with carbon dioxide was increased using a dispergator-type phase-mixer, a patent application was filed for the referred process [84]. The experimental setup and conditions are presented in Chapter 3.3.

4.4.1. Theoretical considerations and calculations

Large amounts (15–20 m³ per one ton of ash) of wastewater that has a considerable CO₂-binding capacity circulate in the hydraulic ash-transportation system. A contact of Ca²⁺ ions present in the alkaline wastewater with CO₂ present in the flue gases results in the reactions described by Eqs (15) and (16):

Figure 19. The amount of CO₂ needed for precipitation of Ca²⁺-ions and neutralization of OH⁻-ions (*Paper V*).

Dissolution of CO₂ into the water depends on the pH, because the forming H₂CO₃* (CO₂*H₂O) dissociates with the formation of CO₃²⁻- and HCO₃⁻ -ions. Herewith,

the overall concentration of carbon C_{CO_2} increases according to the amount of HCO_3^- and CO_3^{2-} -ions formed. Based on the conversion rates α showing which part of the CO_2 present in the solution goes into which particular form (CO_2 , HCO_3^- or CO_3^{2-}), the dependence of the fractional amounts of all carbonate species on the solution pH is presented in Fig. 3. Around the preferable water pH value (8.5), the CO_2 is found in the solution mainly as HCO_3^- . Therefore, the fractional amount of CO_2 necessary for wastewater neutralization can be calculated according to Eq. (16).

Contact of Ca^{2+} -ions with CO_2 leads to precipitation of $CaCO_3$, which is practically insoluble in the water with $pH > 9$. When $pH > 11$, the solution contains mainly CO_3^{2-} ions. This means that at the beginning of the interfacial contact the $CaCO_3$ precipitation can be expected firstly (Eq. (15)). An overall CO_2 demand is calculated as the combination of CO_2 fractional amounts needed for both Ca^{2+} ions precipitation and OH^- -ions neutralization (Fig. 19).

4.4.2. Comparison of the alkaline wastewater carbonation in dispergator- and barboter-type reactors

Comparative experiments with dispergator- and barboter-type reactors indicated that the alkaline ash-transportation waters ($pH=13.0-13.1$, Ca^{2+} content 800–1,020 mg/L) react readily with CO_2 -containing model gases FG1 and FG2 decreasing the content of Ca^{2+} -ions and pH value (Fig. 20a; Table 14).

Table 14: Wastewater treatment with CO_2 -and SO_2 -containing model gases: composition of the solid phase and the liquid phase. (*Paper V*)

In the case of a dispergator-type phase mixer, the content of Ca^{2+} -ions dropped notably – to 10 mg/L after 1 carbonation cycle ($N_{CO_2} = 1.5$) and the pH value

decreased to the acceptable level (about 8) after 3 carbonation cycles ($N_{\text{CO}_2} = 4.5$). A dispergator-type reactor enhances the gas–liquid contact surface thereby promoting mass transfer rates, (Fig. 20b), but as a result of short contact time of the phases (1.25 s per cycle) dissolution of CO_2 is not completed and a higher CO_2 excess N_{CO_2} is needed (Fig. 20a) as compared to a conventional barboter-type column. Nevertheless, by using a dispergator-type reactor by a factor of up to 50 increase in specific intensity (q , $\text{m}^3/\text{m}^3 \cdot \text{h}$) calculated as the volume of processed wastewater per unit of volume of the reactor was achieved. It was found that the filtered solid samples (PCC1–PCC8, see Table 14) contained predominantly CaCO_3 (85–94%).

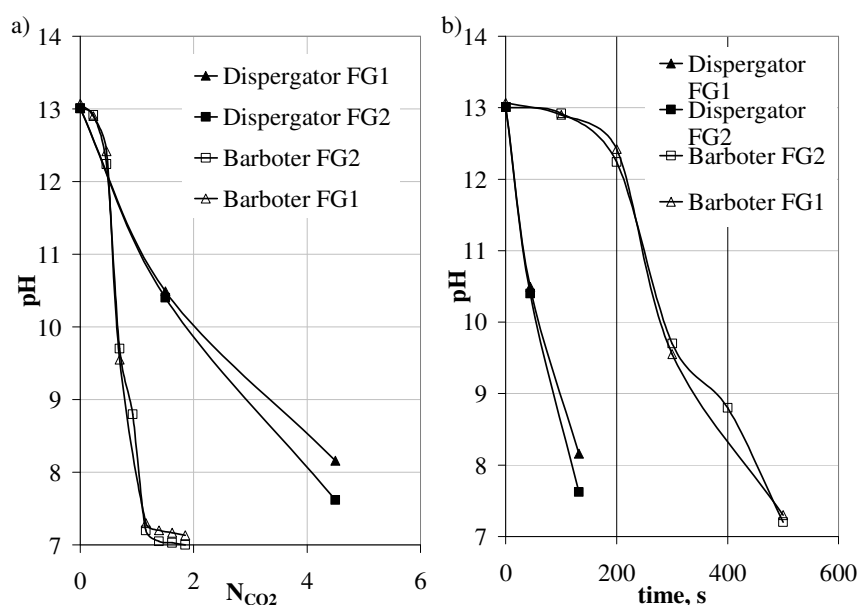

Figure 20. Changes in the wastewater pH during carbonation as a function of (a) CO_2 excess N_{CO_2} and (b) time (calculated per 1 L of wastewater) (Paper V)

4.4.3. Characterization of the solid product of the wastewater carbonation

PCC samples were analyzed for particle size distribution and surface properties. The results showed that the end-point pH value of the carbonation does not influence the size of PCC particles formed in the dispergator-type phase mixer (PCC1 and PCC2, Paper V: Table 2). The samples can be characterized by a homogeneous particle-size distribution: median size $\sim 5 \mu\text{m}$ and mean/median ratio ~ 1 . Presence of SO_2 in the gas mixture considerably influenced the size of the particles (PCC3 and PCC4, Paper V: Table 2): their median size increased noticeably due to agglomeration of particles reaching 8–9 μm . Besides this, the agglomeration effect escalated with decreasing pH. PCC4 sample was not homogeneous, containing particles in the size range 3–310 μm . The PCC samples

from the barboter-type reactor (PCC5–PCC8, *Paper V: Table 2*) had a somewhat larger particle size, which was also influenced by the extent of carbonation: median size was ~6 and 8–10 μm at pH~10 and pH~8, respectively. The presence of SO_2 had a minor influence on the size distribution characteristics of the PCC.

Shape and surface observations confirmed the results of particle-size distribution analysis. The shape of PCC particles from the dispergator-type reactor was influenced noticeably by the extent of carbonation as well as by the presence of SO_2 . Regularly structured particles of PCC were formed in the high pH region in a SO_2 -free environment (Fig. 21a). Extending of the carbonation process led to cleavage of the particles. In the presence of SO_2 most of the individual particles were merged, forming agglomerates (Fig. 21b).

The PCC formed in a barboter-type column is characterized by more homogeneous particles with a distinctive regular rhombohedral crystal structure as compared to the particles formed in the dispergator-type reactor. Shape and surface characteristics were not noticeably influenced by the extent of carbonation or the presence of SO_2 in the model gas (Fig. 21c).

Figure 21. SEM images of the PCC samples formed at different conditions in a dispergator-type phase mixer: PCC1 (a), and PCC4 (b), and a barboter-type column: PCC8 (c)

According to thermodynamic calculations (*Paper I*), precipitation of CaCO_3 in the system wastewater–flue gas can be expected at the starting stages of the interfacial contact at high pH values. If pH has decreased to 7.5–9, the binding capacity of the aqueous phase is almost completely utilized and the increase in CO_2 binding is mainly due to the increase in the amount of dissolved CO_2 and formed HCO_3^- . Also, at a deeper carbonation at pH<9, CaCO_3 becomes more soluble in water and the concentration of Ca^{2+} -ions in the solution starts to rise again as shown in Table 14. Therefore, to avoid agglomeration of the particles and redissolution of CaCO_3 , the alkaline wastewater neutralization process with production of PCC should be divided into two stages: first, CaCO_3 precipitation and separation at high pH values and second, decreasing the residual alkalinity of wastewater to acceptable levels (pH~8–8.5). Producing PCC of specific properties is a complicated process, which needs further research to obtain better understanding of the influence of different conditions on crystallization processes.

4.5. Natural CO₂ binding in ash fields (*Paper III*)

It was shown that the most intensive CO₂ binding takes place in the surface layers within a few centimeters; while in the deeper layers the binding rate is moderate. Pile-up of fresh layers of ash suspension inhibits CO₂ diffusion into the deeper layers and CO₂ binding reactions.

Summer temperature conditions enhance the natural binding of CO₂ into the surface layers of ash deposits, while surrounding temperature does not influence the process in the deeper layers remarkably. Autumn/spring and winter conditions greatly inhibit the rate and extent of the processes under discussion giving prerequisites for chemical reactions and mass/heat transfer.

Table 15: CO₂-binding characteristics of different types of oil-shale ash in natural conditions (average results from experiments in summer, spring/autumn and winter conditions), % (*Paper III*)

Comparison of different kinds of ashes showed that CFBC ashes react readily with atmospheric CO₂, but their total binding capacity is quite low due to only moderate contents of free CaO. Therefore, a substantial part (60-80%) of the CO₂ binding capacity of the CFBC ash could be exhausted at natural conditions (Table 15). In the case of PF ash, which is characterized by a considerable CO₂-binding potential as well as by a low surface area of the particles, most of the free CaO present in the initial ash remains unrealized at given time periods – the average value of BD was within 4.5% after 1 month of deposition (Table 15). Differences in the reactivity of ashes are related to the structure and surface properties of the ash particles (*Paper II*): for instance the SSA of the CFBC ashes is up to ten times that of the PF ashes.

Considering the average results of experiments in model conditions (Table 15), 1 ton of ash binds 9–31 kg CO₂, giving an average of ~100,000 t CO₂ bound by open-air ash deposits annually at the production level of 2006.

4.6. Technological evaluation and expected amounts of CO₂ bound

This study demonstrates that the total amount of naturally-bound CO₂ can reach 52 kg CO₂ per 1 t ash (Table 16). The amount of CO₂ bound by a 1:1 mixture of CFBC ash and PF ash under the natural storage conditions is ca. 22 kg/t.

Implementation of the simple and inexpensive technical methods [87] could double this amount (up to 44 kg/t).

In laboratory experiments, the amount of CO₂ bound by direct carbonation of ash-mixture suspensions with model gases varied from 100 to 160 kg CO₂/t ash depending on the ash type. The average quantity bound was 140 kg/t, which is equivalent to 7.3% of the total and 43.6% of the carbonaceous CO₂ emission, respectively. Application of the above-mentioned methods would radically decrease the remaining content of CO₂-active compounds in the ash. Additional research is necessary to estimate the potential amount of CO₂ that can be bound by the carbonated ash in open-air deposits. We presume that the total amount of CO₂ bound (during carbonation and consequent deposition) would be similar to the sum of CO₂ bound by the direct carbonation of ash–water suspension and water neutralization (192–209 kg/t ash or 10–11% and 60–65% of the total and mineral carbon content, respectively).

Table 16: The amount of CO₂ (A, 10³ t) bound per 1 million t ash and the ratio (B, %) of the total amount (in numerator) to the mineral part (in denominator) of CO₂ emitted at oil-shale combustion (*Paper III*)

The main considerations and the initial data for a design of an industrial pilot-scale plant have been defined and compiled and the principal flow-sheet has been proposed (*Paper IV: Fig. 11*). Considering the real production output, for example

at the Narva Power Plant, it is reasonable to choose the capacity of the test plant to be 120 t/h ash (the capacity of one ash-removal section). The solid : liquid ratio of the pulp to be processed is 1 : 10 which is suitable according to the experiments reprinted here. To guarantee a higher flexibility of the process, it is reasonable to divide the total capacity of the test device over several lines. In the case of four lines, the capacity of one line will be 30 t per hour and the total volume of the reactors will then be approximately 300 m³.

A few important aspects should be taken into account when designing a pilot-scale plant:

- The suspension pH value was chosen to be the main indicator to control the chemical conversion progress. To ensure the optimal conditions for lime slaking and dissociation of Ca²⁺-ions into the bulk solution, the pH values should be carefully chosen for all the reactors composing the line and also optimized during exploitation of the plant.
- To decrease the suspension pH to the optimum final level 8.5 ± 0.3 at the capacity of one line at 30 t/h, it is necessary to introduce 20,000 (at stoichiometric ratio $N_{CO_2} = 1.0-1.2$) to 30,000 m³/h^{STP} ($N_{CO_2} = 1.5$) of flue gases (content of CO₂ 15% vol.).
- Gas-injection density was recommended as the main factor determining the reactor dimensions (suspension-column height and reactor diameter). An initial value of 100 m³/m²*h could be recommended by adjusting the results of the laboratory experiments to a 3–5 times increase in the liquid column height.
- The construction and working regimes of stirrers should be chosen carefully to avoid passive zones at the reactor-column bottom. Also, a smooth-running suspension flow between the reactors should be provided.
- Rotating impellers should avoid the gravity settling of the solid phase and at the same time slow down the vertical movement of gas bubbles. The inlet of flue gases should be placed as deep as possible as to guarantee the maximal and homogeneous interfacial contact (a possible inlet of gas phase is through stirrer shaft and impellers).
- Considering the large volumes of gas–liquid flows, the exiting gases should be passed through a droplet separator, or "de-mister". As the process involves alkaline Ca²⁺-ion-containing solutions and CO₂-containing gases, precipitation in the gas inlet and outlet sections and equipments is highly probable and therefore a periodical high-pressure cleaning is required.

5. CONCLUSIONS

Waste ashes from the oil shale combustion have been characterized as sorbents for CO₂ binding from the flue gases in aqueous mineral carbonation processes. The CO₂ binding potential of various oil-shale ash components has been evaluated. CO₂ emissions from the Estonian oil shale-based power production could be diminished using the waste ash as CO₂ sorbent: the total fractional amount of CO₂ bound (during the carbonation and consequent deposition) averaged to 192–209 kg/t ash or 10–11% and 60–65% of the total and mineral carbon content, respectively.

1. The behavior of lime as the key component of the ash in various conditions was elaborated and the mechanism of process deceleration proposed.
2. The concept of CO₂ mineral sequestration in the oil-shale waste ashes from Estonian power production has been proposed as a way to mitigate the release of the greenhouse gases formed by the burning of fossil fuel oil shale into the atmosphere.
3. The main parameters for the aqueous processes of CO₂ binding – via direct (ash suspensions) or indirect (ash-transportation water) aqueous carbonation of the ash with flue gases and via a natural weathering – have been elaborated. The results can serve as the initial data for an industrial-scale pilot plant design.
4. A new method for the neutralization of the alkaline Ca²⁺-containing wastewater using carbon dioxide from the flue gas has been worked out. It was shown that alkaline ash-transportation water could be considered as a resource for the production of PCC characterized by a regular rhombohedral structure and a homogeneous particle size (~5µm) distribution.

ABSTRACT

Emissions of greenhouse gases and the safe deposition/utilization of solid wastes are among most serious problems caused by extensive usage of low-grade solid fuels in the world heat-and-power production. CO₂ sequestration by mineral carbonation using alkaline waste residues serves both causes, as after stabilization by accelerated carbonation, the leaching behavior of the alkaline waste materials is often improved.

In the Republic of Estonia, a local low-grade carbonaceous fossil fuel Estonian oil shale is used as a primary energy source. Combustion of oil shale is characterized by high specific carbon emissions because of the high content of mineral carbonates present in the oil shale. In Estonia, the power sector is the largest CO₂ emitter and is also a source of huge amounts of waste ash. Depending on the combustion technology (PF or CFBC), the ash contains a total of up to 30%-wt free Ca-Mg oxides. By using CO₂ from the flue gases as a neutralizing agent, the emission of CO₂ could be diminished.

The aims of the current study were to measure the CO₂-binding ability of the waste ashes at different stages of its transportation and under different deposition conditions and to establish a concept for abatement of the CO₂ emissions in Estonian oil shale-based power production via chemical and technological methods.

The results indicated that the waste ash from the oil shale combustion qualifies as effective sorbent for CO₂ capture in aqueous mineral carbonation processes. Model experiments demonstrated that free CaO is the main CO₂-binding component in the ash. However, in addition to free lime, the Ca-silicates (CaSiO₃ and Ca₂SiO₄) and periclase should also be taken into account while calculating the maximal CO₂-binding potential of the oil-shale ash.

The behavior of lime as the key component of the ash in various conditions was also elaborated and the rate-determining mechanism was identified. It was found that the PF ash, which is characterized by low porosity and small size pores is especially affected by the process deceleration. Due to a high concentration of the dissolved salts in the recirculation water, the diffusion of Ca(OH)₂ away from the particle's surface decelerates, which, in its turn, reduces the slaking rate and causes the reactions to take place inside the pores. Precipitation of the reaction products such as CaCO₃ and CaSO₄ may partially or completely coat the particle and prevent the further dissolution of CaO. The porous structure of the CFBC ash particles supports a fast and full hydration of lime as well as the diffusion of Ca²⁺-ions into a solution, and this results in an almost complete carbonation.

The concept of the CO₂ mineral sequestration in the oil-shale waste ashes from Estonian power production has been proposed as a way to mitigate the accumulation of greenhouse gases released by the burning of a fossil fuel, oil shale in the atmosphere. The main parameters for aqueous processes of CO₂ binding – via direct (ash suspensions) or indirect (ash-transportation water) aqueous carbonation of the ash with flue gases and via natural weathering – were

elaborated. The results can serve as initial data for an industrial-scale pilot plant design.

A new method for the neutralization of an alkaline Ca^{2+} -containing wastewater with carbon dioxide present in the flue gas has been worked out. It was shown that the alkaline ash-transportation water could be considered as a source for production of precipitated calcium carbonate (PCC) characterized by a regular rhombohedral structure and homogeneous particle-size ($\sim 5\mu\text{m}$) distribution.

CO_2 emissions from the Estonian oil shale-based power production could be diminished significantly using the waste ash as CO_2 sorbent: the total fractional amount of CO_2 bound (during the carbonation and consequent deposition) averaged 192–209 kg/t ash or 10–11% and 60–65% of the oil shale's total and mineral carbon content, respectively.

KOKKUVÕTE

Madala kütteväärtusega tahkkütuste põletamine energia tootmiseks tekitab mitmeid keskkonnakaitselisi probleeme nagu kasvuhoonegaaside emissioon atmosfääri ja tahke põletusprodukti ohutu ladustamine. Aluseliste jäätmete kasutamine CO₂ mineraliseerimiseks annab mitmese keskkonnakaitselise efekti, vähendades samaaegselt nii CO₂ emissiooni kui ka ladustatava jääkprodukti keskkonnaohtlikkust.

Eestis emiteeritavast süsihappegaasi hulgast pärineb suurem osa energeetikasektorist, mille põhitoomeks on põlevkivi. Põlevkivil on võrreldes teiste kütustega suurem süsinikuemissiooni koefitsient tema kõrge mineraalse CO₂ ehk karbonaatide sisalduse tõttu. Olenevalt põletamistehnoloogiast sisaldab tekkiv tuhk kuni 30% karbonaatide termilisel lagunemisel tekkivaid Ca- ja Mg-oksiide. Põlevkivi põletamisel tekkiva CO₂ sidumine tuha leeliseliste komponentidega võimaldab vähendada nii atmosfääri saastava CO₂ emissiooni kui ka ladustatava tuha keskkonnaohtlikkust.

Antud töö ülesandeks oli hinnata tuha CO₂ sidumisvõimekust erinevates transpordietappides ja ladustamistingimustes ning koostada kontseptsioon CO₂ emissiooni piiramiseks Eesti põlevkivienergeetikas keemilis-tehnoloogiliste vahenditega.

Tulemused näitasid, et põlevkivi tolmu- ning keevkihtpõletamisel formeeruvad tuhad on oma koostise ning omaduste poolest sobivad sorbendid sidumaks CO₂ samas tekkivatest suitsugaasidest. Mudelkatsete põhjal on tuha kõige aktiivsemaks komponendiks kaltsiumoksiid, kuid tuha CO₂ sidumispotentsiaali hindamisel tuleks arvestada ka kaltsiumsilikaatide (CaSiO₃ ja Ca₂SiO₄) ning periklaasiga.

Protsessi pidurdumismehhanismi selgitamiseks uuriti lubja, kui antud süsteemis ühe olulisima tuha komponendi, käitumist erinevates tingimustes. Leiti, et vähepoorsete tolmpõletustuhkade puhul pidurdub karboniseerimisprotsess märgatavalt. Kõrge soolsusega ringlusvee toimel Ca(OH)₂ difusioon lahusesse aeglustub, mis vähendab omakorda lubja kutsumiskiirust ning tingib reaktsioonide toimumise pooride suudmeis. Sadestuvad reaktsiooniproduktid nagu CaCO₃ ja CaSO₄ võivad kas osaliselt või täielikult peatada vaba lubja edasise lahustumise. Keevkihttuhkade poorne struktuur soodustab nii lubja kiiret ja täielikku kustumist kui ka Ca²⁺-ioonide difusiooni lahusesse, tagades seega peaaegu täieliku karboniseerimise.

Koostati kontseptsioon süsihappegaasi emissiooni vähendamiseks põlevkivienergeetikas samas tekkivate tuhade baasil kõigi CO₂ mineraliseerimisvõimaluste süsteemse arvestamisega. Töötati välja põhiparameetrid CO₂ märgsidumiseks suitsugaasidest nii otsese (tuha vesisuspensioonid) kui ka kaudse (tuha transpordived) karboniseerimise teel. Tulemused on kasutatavad alusmaterjalina tööstusliku katseaparatuuri kavandamisel.

Töötati välja uudne meetod leeliselise Ca²⁺-ioone sisaldava heitvee intensiivseks neutraliseerimiseks suitsugaasides sisalduva süsinikdioksiidiga. Näidati, et

leeliseline tuha transpordivesi on perspektiivne tooraine romboedrillilise struktuuri ning homogeense tükisuurusega ($\sim 5\mu\text{m}$) sadestatud kaltsiumkarbonaadi (PCC) tootmiseks. CO_2 emissiooni Eesti põlevkivienergeetikast on võimalik vähendada kasutades samas tekkivaid tuhkasid CO_2 sorbentidena: kokku on võimalik siduda (karboniseerimisprotsessis ja ladustamise käigus) 192–209 kg CO_2 tonni tuha kohta või 10–11% ja 60–65% vastavalt põlevkivi põletamisel eralduva CO_2 koguemissioonist ja põlevkivi mineraalosalast pärinevast CO_2 emissioonist.
